Abstract

Beta-blockers are used to treat acquired heart failure in adults, though their role in early muscular dystrophy cardiomyopathy is unclear. We treated 2 different dystrophic mouse models which have an associated cardiomyopathy (mdx: model for Duchenne Muscular Dystrophy, and Sgcd-/-: model for limb girdle muscular dystrophy type 2F) and wild type controls (C57 Bl10) with the beta blocker metoprolol or placebo for 8 weeks at an early stage in the development of the cardiomyopathy. Left and right ventricular function was assessed with cardiac magnetic resonance imaging (MRI) and in-vivo myocardial calcium influx with manganese enhanced MRI. In the mdx mice at baseline there was reduced stroke volume, cardiac index, and end-diastolic volume with preserved left ventricular ejection fraction. These abnormalities were no longer evident after treatment with beta-blockers. Right ventricular ejection fraction was reduced and right ventricular end-systolic volume increased in the mdx mice. With metoprolol there was an increase in right ventricular end-diastolic and end-systolic volumes. Left and right ventricular function was normal in the Sgcd-/- mice. Metoprolol had no significant effects on left and right ventricular function in these mice, though heart/body weight ratios increased after treatment. In-vivo myocardial calcium influx with MEMRI was significantly elevated in both models, though metoprolol had no significant effects on either. In conclusion, metoprolol treatment at an early stage in the development of cardiomyopathy has deleterious effects on right ventricular function in mdx mice and in both models no effect on increased in-vivo calcium influx. This suggests that clinical trials need to carefully monitor not just left ventricular function but also right ventricular function and other aspects of myocardial metabolism.

Introduction

In Duchenne muscular dystrophy the absence of dystrophin causes subclinical or clinical dilated cardiomyopathy [1,2]. Also, mutations in one of the genes for α-, β-, γ- or δ-sarcoglycan, a heterogeneous group of autosomal recessive limb girdle muscular dystrophies (LGMD2C-F), cause severe dilated cardiomyopathy at a young age in addition to muscular dystrophy, especially in those patients with LGMD2F caused by mutations in the δ-sarcoglycan gene [1–3].

Beta-blockers are established treatments for acquired heart failure [4] though the role in inherited cardiomyopathies is less clear. It has been suggested that for certain dystrophin mutations which predispose to cardiomyopathy, early treatment including beta-blockers is of benefit [5]. We have shown that in mdx mice, which lack the protein dystrophin as in Duchenne muscular dystrophy that there are benefits in terms of left ventricular pressure-volume derived data with early beta-blocker treatment, though detrimental effects in the delta sarcoglycan deficient mouse model (Sgcd-/-, model for limb girdle muscular dystrophy type 2F) [6]. This suggests that not all underlying genotypes may respond beneficially to beta-blockers.

However, left ventricular pressure and volume measurements are not the only physiological measurements that can assess the effects of a systemic treatment. Right ventricular function is frequently abnormal in cardiomyopathy. Both left and right ventricular function can be assessed non-invasively with cardiac magnetic resonance imaging (MRI). Increased intracellular calcium is an important feature of muscular dystrophy cardiomyopathy and plays a central role in its pathophysiology [7]. Manganese-enhanced magnetic resonance imaging (MEMRI) can assess in-vivo calcium influx using 2 properties of the manganese ion [8]. Manganese enters cardiomyocytes through calcium channels, and is also a T1 contrast agent with MRI. Thus, manganese influx results in a relative increase in contrast-enhancement on T1 weighted images.

The purpose of this study was to treat 2 different mouse models of muscular dystrophy cardiomyopathy with beta-blockers at an early stage in the development of the cardiomyopathy to determine if there are beneficial effects on left and right ventricular...
function and to determine whether beta-blockers reduced in-vivo myocardial calcium influx.

Materials and Methods

Animals

Male mdx (n = 15) from Jackson laboratories (Bar Harbor, ME, USA), Sgcd/- mice (n = 11) and C57 Bl10 mice [Jackson Laboratories] (n = 6) were treated with metoprolol and compared to age matched controls (mdx (n = 21), Sgcd-/- (n = 20), C57 Bl10 (n = 19). Mice were housed under controlled temperature (17–28 °C) and light conditions (12:12h light: dark cycle). Animals had free access to food and water. The investigations conformed with the Guide for the Care and Use of Laboratory Animals published by the US National Institutes of Health [NIH Publication No.85–23, revised in 1985 and was performed under the terms of the Animals (Scientific Procedures) Act 1986, authorized by the Home Secretary, Home Office UK]. All experiments were performed at the animal care facility of Newcastle University, UK. The work was approved by the Ethical Review Committee of Newcastle University.

Drug treatment

Metoprolol (2.5 mg/kg/day) (M5391, Sigma-Aldrich) was administered orally via the drinking water, which was refreshed every 48 hours. From our previous studies [9–11] we have been able to establish that mice (housed under the conditions in our animal unit) drink an average volume of 2.5 ml/day drinking water. Mice were weighed fortnightly and the concentration of metoprolol in the drinking water was adjusted accordingly.

Treatment was initiated in the mdx mice at 16 weeks and at 8 weeks in the Sgcd-/- mice, timepoints which are early in the development of left ventricular dysfunction [12]. Treatment was continued for 8 weeks and cardiac function was assessed in the mdx mice at 24 weeks of age and 16 weeks in Sgcd-/- mice; ages at which cardiac function has previously been shown to be impaired in these mouse models [6,10]. The C57 Bl10 mice were aged 12 weeks at the start of the treatment as an intermediate age between the mdx and Sgcd-/- mice.

MRI

Following induction of anaesthesia with 5% isofluorane in an anaesthetic chamber, mice were cannulated via the tail vein and laid prone on a cradle that allowed monitoring of body temperature, respiratory rate and heart rate heart rate (Dazai Research Instruments, Toronto, Canada). Mice were placed in the magnet and anaesthesia was maintained using 1–1.8% isofluorane via a nose cone. Their body temperature was maintained using a warm air blower. Images were acquired on a 7 Tesla horizontal bore Varian microimaging system equipped with a 12-cm microimaging gradient insert (maximum gradient 40 gauss/cm), (Varian Inc., Palo Alto, CA, USA). Mice were scanned in a 39 mm diameter quadrature birdcage volume coil (Rapid Biomedical GmbH). Following power calibration and global shimming a series of four pilot transverse images were acquired over the heart. Single slice coronal and sagittal images were then obtained in order to view the apex and mitral valve planes. These images were used to plan for the true short axis plane. To measure ventricular function, up to twelve contiguous short axis slices were acquired to cover the entire left and right ventricles using a spoiled gradient-echo cine sequence (TR = 5 ms, TE = 1.42 ms, flip angle 15°, FOV 30 x 30 mm, data matrix 128 x 128, 1 mm slice thickness). Images were ECG triggered to the R wave with a cine delay of 15 ms and typically 30 phases were acquired distributed through the cardiac cycle. Images were zero-filled to a matrix size of 256 x 256. Scans were converted to matfiles using a matlab script (kindly provided by Johannes Riegler, UCL) and analysed using the freely available analysis software Segment v1.1 (http://segment.heiberg.se) to give LV and RV functional parameters.

Segment automatically delineated the endocardial and pericardial borders at end systole and end diastole and manual adjustments were made if necessary. LV mass, RV and LV volumes, ejection fractions and cardiac output were calculated.

Manganese enhanced MRI (MEMRI)

Manganese chloride (60 mM, Sigma-Aldrich 244589) was given by intravenous infusion through the tail vein canula at a flow-rate of 0.6 ml/hour. Flow time was adjusted according to weight to give a total dose of 190 nmol/g body weight (for example, for a 30 g mouse, this would result in a 9.5 minute infusion). Single slice gradient echo short axis images at the level of the papillary muscles (T₁ weighted parameters: TR = 35 ms, TE = 3.5 ms, flip angle 60°, FOV 30 mm x 30 mm, data matrix 128 x 128, 1 mm slice thickness, 6 averages) were taken. Prior to manganese infusion four baseline images were acquired in order to average any variations due to changes in TR as a result of fluctuations in heart rate. Infusion was begun and images were taken at 2.5 mins, 5 mins and then at 5 minute intervals thereafter, for 30 minutes. A relative increase in T₁ weighted contrast indicates increased manganese uptake. The time course stack of images were analysed in Imagej [http://rsb.info.nih.gov/ij]. An area of interest was drawn to fit inside the myocardium and average signal intensity was measured. If necessary, minor adjustments of this drawn region were made for subsequent images in the stack and the increase in myocardial contrast enhancement was expressed as a percentage increase from the average of the four baseline images (which showed little or no variation). MEMRI data is expressed as an enhancement ratio over baseline.

Statistics

Where appropriate, data was normalized to body weight. All data are reported as mean ± [standard error]. Differences between animal and treatment groups were compared by univariate general linear model ANOVA with Bonferroni-Sidak posthoc testing, and statistically significant findings of P<0.05 are reported.

Results

Ventricular hypertrophy in untreated mdx mice and metoprolol-treated Sgcd/- mice

Metoprolol treatment was well tolerated and there were no early deaths in the treated mice. Sgcd-/- mice had lower body weights compared to C57 Bl10 controls (table 1). Compared to untreated C57 Bl10 mice, mdx mice had evidence of ventricular hypertrophy (post mortem combined weight of right and left ventricles) with elevated heart to body weight ratios with and without metoprolol, and the Sgcd-/- mice had an increased heart to body weight ratio after metoprolol only (table 1). Mean anesthetized heart rates for all groups are shown in Figure 1a.

In mdx mice metoprolol has beneficial effects on left ventricular size and function though detrimental effects on right ventricular size, whilst in Sgcd-/- mice metoprolol increases left ventricular size.

C57 Bl10. Beta-blockers had no significant effects on left or right ventricular function or left ventricular mass.

Mdx. The cardiomyopathy in the untreated mdx mice was characterized by a smaller left ventricular cavity in diastole,
Significantly higher than C57 Bl10 and ventricular end-diastolic volume such that this parameter was now these parameters and indeed there was a further increase in right ventricular end-systolic volume at baseline (Figure 3, and 4a and b). Metoprolol did not normalize fraction and increased right ventricular end-systolic volume at stages following the start of the infusion (p = ns, ANOVA). (Figure 5 a-d) as previously demonstrated [13], indicating in-vivo increased calcium influx occurring at an early stage in the development of the cardiomyopathy. This was not significantly affected in either group by treatment with metoprolol (p = ns, ANOVA).

**Discussion**

In two mouse models of muscular dystrophy cardiomyopathy treated with the beta-blocker metoprolol at an early stage in the development of the cardiomyopathy, we show that there are differences in left and right ventricular function and the responses to treatment. In the mdx mice without treatment there is ventricular hypertrophy, reduced left ventricular stroke volume with a small left ventricular cavity size, normal left ventricular ejection fraction but reduced right ventricular ejection fraction. Consistent with our previous invasive catheter based studies there are benefits of metoprolol on left ventricular function in the mdx mice, but here we also demonstrate deterioration in right ventricular function. The Sgcd/- mice develop ventricular hypertrophy with metoprolol (compared to untreated C57 Bl10 mice), but have normal left and right ventricular function without treatment with no significant effects of treatment on left or right ventricular function relative to C57 Bl10 mice. Despite these heterogeneous patterns of ventricular function in the 2 models, both exhibit increased intracellular calcium influx that is unaffected by metoprolol. Thus, overall responses to metoprolol in both models are largely either absent or potentially detrimental.

Right ventricular function

In clinical heart failure, right ventricular dysfunction is an important predictor of outcomes [14]. In muscular dystrophy cardiomyopathy, right ventricular dysfunction may be an important early feature. In Becker’s muscular dystrophy cardiac involvement appears to develop first in the right ventricle when seen in younger patients, and left ventricular involvement develops at a later age [15,16]. In the mdx mouse model, right ventricular dysfunction has also been shown to be an important early feature, and similarly to the clinical studies above, right ventricular dysfunction precedes left ventricular dysfunction [17]. This suggests that the pathophysiology of right ventricular dysfunction is due to an intrinsic right ventricular process as opposed to right ventricular dysfunction developing secondary to left ventricular dysfunction in the setting of secondary pulmonary hypertension and increased right ventricular afterload. The detrimental effect of metoprolol on this early marker of cardiomyopathy in the mdx mice would suggest caution for early beta-blocker usage. One potential explanation linking the apparent improvement in left ventricular function and deterioration in right ventricular function is that the relatively low stroke volume from the left ventricle without treatment protects the abnormal and susceptible right ventricle from excessive volume overload. However, the beta-blockers restore stroke volume and cardiac output to wild type levels and this increased flow to the right side of the heart then causes greater dilatation of the right ventricle. This is a phenomenon that is well recognized when patients with biventricular dysfunction have left ventricular output restored with a left ventricular assist device that then aggravates right ventricular dysfunction [18].

Figure 2. Effect of metoprolol treatment on left ventricular function. (A) Left ventricular volume to body weight (BW) ratios; (B) Ejection fraction; (C) Cardiac output (CO) to body weight ratio. Reductions in left ventricular end-diastolic and (LV EDV) and left ventricular stroke volume index (LV SV) in untreated mdx mice were no longer evident after metoprolol treatment. In untreated Sgcd/- mice there was normal left ventricular function, and after treatment with metropolol there were increases in end-diastolic, end-systolic (LV ESV) and stroke volume indexes relative to untreated mdx mice. In-vivo myocardial calcium influx

Increased calcium influx into the cardiac myocyte is an important phenomenon in muscular dystrophy cardiomyopathy leading to progression of left ventricular dysfunction. Recurrent membrane injury leads to an increased influx of calcium [22] which then causes downstream effects such as activation of calcium-dependent hypertrophic pathways [23], reactive oxygen species [24] and cell death through necrosis with mitochondrial defects [25]. MEMRI can be used to non-invasively assess myocardial calcium influx [8], and we have recently shown that it is increased in these 2 mouse models [13]. Despite the similar increase in calcium influx in both models we showed that there were likely different mechanisms responsible for this in the 2 models. In the Scgd−/− mouse there was less reduction in contrast enhancement with the L-type calcium channel blocker diltiazem compared to the mdx or wild type mice. Also, higher heart rates played some role in the increased contrast enhancement in the Scgd−/− mouse, though heart rate was seen not to account for all the increase when this was brought down to wild type levels. The current study suggests that this important pathophysiological mechanism leading to left ventricular dysfunction is unaffected by beta-blockade. We do not know if successful treatment with beta-blockers in situations where it is proven that they have beneficial effects on outcomes (such as adult heart failure) reduces calcium influx, and so the exact relevance of this finding pending further studies is unclear.

Conclusions

Treatment with the beta-blocker metoprolol at an early stage in the development of the cardiomyopathy leads to worsening right ventricular function in the mdx mouse, and in both models has no effect on calcium influx. This suggests that clinical studies with beta-blockers and other heart failure medications should comprehensively evaluate not only left ventricular function but also right ventricular function and other aspect of myocardial metabolism.
