Abstract. The calibration of field instruments used to measure concentrations of OH and HO$_2$ worldwide has traditionally relied on a single method utilising the photolysis of water vapour in air in a flow tube at atmospheric pressure. Here the calibration of two FAGE (fluorescence assay by gaseous expansion) apparatuses designed for HO$_x$ (OH and HO$_2$) measurements have been investigated as a function of external pressure using two different laser systems. The conventional method of generating known concentrations of HO$_x$ from H$_2$O vapour photolysis in a turbulent flow tube impinging just outside the FAGE sample inlet has been used to study instrument sensitivity as a function of internal fluorescence cell pressure (1.8–3.8 mbar). An increase in the calibration constants $C_{\text{OH}}$ and $C_{\text{HO}_2}$ with pressure was observed, and an empirical linear regression of the data was used to describe the trends, with $\Delta C_{\text{OH}} = (17 \pm 11)\%$ and $\Delta C_{\text{HO}_2} = (31.6 \pm 4.4)\%$ increase per millibar (uncertainties quoted to $2\sigma$). Presented here are the first direct measurements of the FAGE calibration constants as a function of external pressure (440–1000 mbar) in a controlled environment using the University of Leeds HIRAC chamber (Highly Instrumented Reactor for Atmospheric Chemistry). Two methods were used: the temporal decay of hydrocarbons for calibration of OH, and the kinetics of the second-order recombination of HO$_2$ for HO$_2$ calibrations. Over comparable conditions for the FAGE cell, the two alternative methods are in good agreement with the conventional method, with the average ratio of calibration factors (conventional : alternative) across the entire pressure range, $C_{\text{OH( conv)}}/C_{\text{OH( alt)}} = 1.19 \pm 0.26$ and $C_{\text{HO}_2(\text{conv})}/C_{\text{HO}_2(\text{alt})} = 0.96 \pm 0.18$ ($2\sigma$). These alternative calibration methods currently have comparable systematic uncertainties to the conventional method: ~28 % and ~41 % for the alternative OH and HO$_2$ calibration methods respectively compared to 35 % for the H$_2$O vapour photolysis method; ways in which these can be reduced in the future are discussed. The good agreement between the very different methods of calibration leads to increased confidence in HO$_x$ field measurements and particularly in aircraft-based HO$_x$ measurements, where there are substantial variations in external pressure, and assumptions are made regarding loss rates on inlets as a function of pressure.

1 Introduction

Short-lived free radicals play a crucial role in determining the composition of the atmosphere. The catalytic cycle of HO$_x$ (= OH + HO$_2$) radicals is of central importance to tropospheric chemistry. OH acts as the primary daytime oxidant, initiating the degradation of most trace gases and thereby controlling their atmospheric concentrations and lifetimes. The short lifetime of the radicals generate HO$_x$ concentrations which are uninfluenced by transport; therefore repro-
duction of observed HOx concentrations can be an excellent test of any chemical model (Heard and Pilling, 2003). However, it should be mentioned that agreement between measured and modelled [HO\textsubscript{x}] could be fortuitous as both sources and sinks of HOx radicals could be simultaneously under- or overestimated. The development of detection techniques that permit the speciation of a wider range of atmospheric components (e.g. volatile organic compounds (VOCs) and aerosols), together with OH reactivity measurements, can help to further constrain modelling studies and reduce the potential for the coincidental agreement. OH has been detected by long-path differential absorption spectroscopy (DOAS) in the field (Brauers et al., 1996; Dorn et al., 1996) and in the SAPHIR chamber (Schlosser et al., 2009), and chemical ionisation mass spectrometric techniques (CIMS) have also been used in field observations (Eisele and Tanner, 1991; Berresheim et al., 2002; Sjostedt et al., 2007; Kukui et al., 2008). However, a majority of field measurements have been made using laser-induced fluorescence (LIF) spectroscopy, and intercomparisons exist which have validated the technique against DOAS and CIMS in both chamber (Schlosser et al., 2007, 2009; Fuchs et al., 2012) and field environments, including aircraft-based measurements (Eisele et al., 2001, 2003). Low concentrations and potential interferences (Fuchs et al., 2011; Mao et al., 2012; Whalley et al., 2013) make HOx measurements challenging. In addition, most HOx detection methods are not absolute, and hence calibration is required.

Fluorescence assay by gas expansion, FAGE, is a low-pressure LIF technique commonly used for the detection of OH and HO\textsubscript{2} radicals (Heard, 2006, and references therein). The low concentrations of ambient OH (∼10\textsuperscript{6} molecule cm\textsuperscript{-3}) require a viable measurement technique to discriminate between laser-scattered light and small signal levels. Originally this was attempted by exciting OH to the first vibrational level in the A state at 282 nm (\(A^2\Sigma^+ \left(\nu' = 1\right) \rightarrow X^2\Pi, \left(\nu'' = 0\right)\) OH transition) and observing off-resonant fluorescence at ∼308 nm using an interference filter to help discriminate against scattered laser radiation (Davis et al., 1976). Although non-resonant LIF has been successful in stratospheric applications (Wennberg et al., 1994), in the troposphere 282 nm photolysis of ozone (and subsequent reaction of \(O(1D)\) with water vapour) generates an unacceptably high interfering OH signal, and on-resonant LIF with excitation at 308 nm is used instead. Expanding the sample through a pinhole to low pressure (∼1–2 Torr) increases the fluorescence lifetime of the A state beyond the laser scatter pulse, allowing for temporal discrimination against the resonant 308 nm excitation pulse (\(A^2\Sigma^+ \left(\nu' = 0\right) \rightarrow X^2\Pi, \left(\nu'' = 0\right)\) OH transition). Injection of an OH scavenger (e.g. C\textsubscript{3}F\textsubscript{6}) allows quantification of any laser-generated OH interference (Mao et al., 2012; Novelli et al., 2014). HO\textsubscript{2} is converted into OH via reaction with added NO:

\[
\text{HO}_2 + \text{NO} \rightarrow \text{OH} + \text{NO}_2 \quad (R1)
\]

and the resultant OH is detected in the same way. Detection of OH and HO\textsubscript{2} either simultaneously or in series can be achieved using the same LIF detection axis (measurements in series; Creasey et al., 1997a), with two separate LIF axes within the same cell (simultaneous; Stevens et al., 1994) or with two separate detection cells (simultaneous; Whalley et al., 2010).

LIF is a very sensitive but non-absolute detection method, and therefore each channel of the instrument needs to be calibrated. The vacuum-ultraviolet (VUV) photolysis of H\textsubscript{2}O vapour was originally developed for the calibration of HOx measurement instruments in the 1990s (Aschmutat et al., 1994; Schultz et al., 1995; Heard and Pilling, 2003). Since then the methodology has become the HOx measurement community standard. Upon the photolysis of a known H\textsubscript{2}O vapour concentration (in synthetic air at atmospheric pressure) by a mercury (Hg) Pen-Ray lamp at 184.9 nm, OH and HO\textsubscript{2} are produced in unity ratio (Fuchs et al., 2011) via Reactions (R2) and (R3) (Schultz et al., 1995):

\[
\begin{align*}
\text{H}_2\text{O} + h\nu &\xrightarrow{\lambda=184.9\ nm} \text{OH} + \text{H}, \\
\text{H} + \text{O}_2 (\text{M}) &\xrightarrow{M=\text{N}_2\text{O}_2} \text{HO}_2(\text{M}).
\end{align*}
\]

The radicals are then sampled by the HOx instrument at atmospheric pressure; the concentrations of OH and HO\textsubscript{2} produced can be determined using Eq. (1):

\[
[\text{OH}] = [\text{HO}_2] = \sigma_{\text{H}_2\text{O},\ 184.9\ nm} \Phi_{\text{OH}} F_{184.9\ nm} \Delta t, \quad (1)
\]

where \([\text{H}_2\text{O}]\) is the water vapour concentration; \(\sigma_{\text{H}_2\text{O},\ 184.9\ nm}\) is the known absorption cross section of H\textsubscript{2}O vapour at 184.9 nm ((7.22 ± 0.22) × 10\textsuperscript{-20} cm\textsuperscript{2} molecule\textsuperscript{-1} (Cantrell et al., 1997; Creasey et al., 2000)); \(\Phi_{\text{OH}} (= \Phi_{\text{HO}_2} = 1)\) is the photodissociation quantum yield of OH and HO\textsubscript{2} (Fuchs et al., 2011); \(F_{184.9\ nm}\) is the photon flux of 184.9 nm light; and \(\Delta t\) is the exposure time of the air to the Hg lamp output. There are two main methodologies used for obtaining the product \(F_{184.9\ nm}\); \(\Delta t\) in Eq. (1). In the first, the two parameters are measured separately, \(F_{184.9\ nm}\) using a calibrated phototube and \(\Delta t\) using knowledge of the volumetric flow rate and geometric parameters of the flow tube (Stevens et al., 1994). In the other, a chemical actinometer is used to obtain the product directly, with both O\textsubscript{3} and N\textsubscript{2}O photolysis at 184.9 nm used to generate either O\textsubscript{3} or NO, which is subsequently detected using commercial analysers, with good sensitivity (Creasey et al., 1997a; Hofzumahaus et al., 1997; Heard and Pilling, 2003; Falloona et al., 2004). There are two main methods for delivery of the OH radicals to the FAGE inlet at atmospheric pressure, either using a laminar or turbulent flow tube. In the laminar flow regime there is a radial gradient in the OH concentration for which the so-called profile factor (\(P\)) has to be quantified (Holland et al., 1995; Creasey et al., 1997a), whereas in a turbulent flow system the radial OH concentration is constant except very close to the walls.
Alternative calibration methods have also been developed, but typically not deployed in the field, and examples of these will be employed in the current study. A detailed evaluation of calibration techniques has been presented by Dusanter et al. (2008). In some of the earliest field measurements, Hard et al. (1995) developed a calibration method based on hydrocarbon decays. The concentration of a hydrocarbon with a known and well-characterised rate coefficient for reaction with OH, \( k \) (in this case 1,3,5-trimethylbenzene), was measured as a function of time using gas chromatography, allowing determination of all the parameters in Eq. (2) with the exception of [OH]. The rate of loss of a hydrocarbon (HC) through reaction with OH is given by Eq. (2):

\[
\frac{d[HC]}{dt} = k[OH][HC].
\]  

(2)

This methodology has also been applied more recently to FAGE validation measurements in the EUPHORE chamber (Bloss et al., 2004).

For HO\(_2\) the well-defined second-order recombination rate coefficient for Reaction (R4) can be used to determine [HO\(_2\)], where for a second-order reaction the half-life of the decay is related to the initial starting concentration.

\[
\text{HO}_2 + \text{HO}_2 \rightarrow \text{H}_2\text{O}_2 + \text{O}_2
\]  

(R4)

In a short set of experiments, Pilling et al. (2005) generated HO\(_2\) from the photolysis of formaldehyde in the EUPHORE chamber and observed the second-order HO\(_2\) decay with a FAGE instrument. The decays were in good agreement with the calibrated HO\(_2\) measurements, but no systematic studies have been undertaken using this reaction as a calibration method.

The deployment of the FAGE technique for aircraft-based measurements (Faloona et al., 2000; Commane et al., 2010; Martinez et al., 2010) raises two issues. First, the need to sample air from outside of the boundary layer of the aircraft fuselage requires a significant length of flow tube before the gas sample is interrogated by the laser beam. Secondly, the pressure in the FAGE cell will vary as the aircraft changes altitude (e.g. 0–7 km, 1.3–2.8 mbar internal cell pressure range, from Commane et al., 2010), altering the instrumental sensitivity (Commane et al., 2010; Martinez et al., 2010) owing to changes, for example, in the nature of the initial expansion into the FAGE apparatus. The current design of the flow tube calibration method is limited to delivering the calibrated [OH] at atmospheric pressure; however, by using different nozzle pinhole diameters (typically 0.2–1.0 mm) it is possible to alter the pressure in the FAGE cell over the range typically encountered during a flight. Importantly, this method does not compensate for the changing pressure differential across the inlet nozzle experienced during a flight and what effect this might have on the expanding gas before it reaches the FAGE cell. The possible changes in radical surface losses due to the change in inlet pinhole diameter are also assumed to be negligible.

Potential systematic uncertainties around the application of calibrations performed at atmospheric pressure to HO\(_x\) data obtained whilst sampling from different pressures (e.g. in flight) highlight the need to obtain calibrations at relevant external pressures. Martinez et al. (2010) have investigated the effect of external pressure on instrument sensitivity by calibrating during flight, reporting an increase in the instrument sensitivity to OH in the free troposphere, compared to the boundary layer. It was not concluded whether this was an effect of the calibration source used (conventional H\(_2\)O vapour photolysis) or the instrument itself; however the increase was not characterised by the conventional calibrations performed on the ground before the flight.

We report here an intercomparison of HO\(_x\) calibrations based on the conventional flow tube methodology, using different inlet nozzle diameters to vary the internal fluorescence cell pressure, with two alternative calibration methods. Analysis of the decays of hydrocarbons was used to determine [OH], while analysis of the kinetics of HO\(_2\) decay by self-reaction following the photolysis of formaldehyde was used to determine [HO\(_2\)]. The studies took place in the Highly Instrumented Reactor for Atmospheric Chemistry (HIRAC), which is a custom-built atmospheric simulation chamber providing the unique ability to simultaneously vary pressure and temperature whilst measuring the short-lived free radical species OH, HO\(_2\) and NO\(_3\) (Glowacki et al., 2007a; Malkin, 2010; Malkin et al., 2010). These features make HIRAC ideally suited to the study of the kinetics and mechanisms of atmospherically relevant reactions and the calibration, validation and development of atmospheric measurement instrumentation.

2 HIRAC and FAGE instrumentation

2.1 HIRAC

Experiments were conducted in HIRAC, a stainless-steel chamber with a total volume of 2.25 m\(^3\) and total internal surfaces of 13 m\(^2\) (\(S/V \sim 5.8\) m\(^{-1}\)). The chamber could operate over a wide range of pressures (10–1000 mbar), with multiple access ports used to connect an array of instrumentation and monitoring equipment (pressure gauges, thermocouples etc.). Further details on the construction can be found in Glowacki et al. (2007a) and Malkin et al. (2010).

The photolysis lamps, housed in eight quartz tubes mounted radially inside the reactive volume, were used to initiate photochemistry. The lamps were interchangeable depending on the target molecules; lamps, with primary emissions centred at 254 and 290 nm (GE Optica, GE55TS/HO and Philips, TL40W/12 RS), were used for the alternative OH and HO\(_2\) calibration methods respectively (Sects. 3.2 and 3.3). The output of the lamps was temperature dependent outside of a narrow temperature range (\(\sim 35–39^\circ\)C), and so the housings were flushed with N\(_2\) to regulate the temperature.
and remove photolabile species. A photolysis-lamp-induced chamber temperature increase of ∼2 K was seen over the course of a typical experiment (<40 min), and was therefore considered negligible compared to the temperature of the chamber on any given day (293 ± 5 K).

Investigations into radical gradients across the HIRAC chamber have been conducted using direct FAGE measurements of OH produced from both photolytic (methyl nitrite) and non-photolytic (O₃+trans-2-butene) sources using an extended inlet (800 mm) to probe across the chamber diameter. No significant OH radical gradient was observed until the FAGE sampling nozzle was ∼200 mm from the wall and a maximum ∼15 % decrease (compared to the centre of the chamber) was seen when the sampling inlet was flush with the chamber walls. Other than being close to the walls, the lack of gradient in OH radicals from both photolytic and non-photolytic sources provides direct evidence of the homogeneity of the lamp radiation profile and efficacy of mixing in the chamber, whilst showing that the standard FAGE inlet (280 mm, Sect. 2.2) samples well into the homogeneous area.

Ozone was monitored using a UV photometric O₃ analyser (Thermo Electron Corporation 49C, detection limit (d.l.) = 1.0 ppbv at 60 s averaging). The O₃ analyser had been calibrated using a commercial ozone primary standard (Thermo Electron Corporation 49i-PS), and an intercomparison with the Fourier transform infrared (FTIR) spectroscopy within HIRAC was linear (Glowacki et al., 2007a). A chemiluminescence NOₓ analyser (TEC 42C, d.l. = 50 pptv at 60 s averaging) was used to determine that levels of NOₓ (= NO + NO₂) were characteristically below the detection limit of the apparatus.

A calibrated gas chromatography instrument with flame ionisation detector (GC-FID, Agilent Technologies, 6890N) was used for the online detection of reactants (Sect. 3.2) using an evacuated sampling loop into which gas from the chamber was expanded. The GC was fitted with a CP-SIL-5 column (50 m, 0.32 mm, 5 µm) using He carrier gas and a constant oven temperature (40–75 °C depending on the hydrocarbon being detected) and was able to provide hydrocarbon measurements on a 2–6 min time resolution. Supporting measurements of iso-butene and (CH₃)₃COOH were made via a long-path FTIR absorption facility. The FTIR spectrometer (Bruker, IFS/66) was coupled to a Chemin-type multipass cell (Glowacki et al., 2007b) and spectral resolution was maintained at 1 cm⁻¹ across all experiments, using 32 co-added spectra for a 30 s time resolution.

Calibration experiments were conducted over a pressure range of 440–1000 mbar in an ultra-high-purity (UHP) 1 : 4 synthetic air mixture of O₂ (BOC, zero-grade, > 99.999 %) and N₂ (BOC, zero-grade, > 99.998 %) to match the range of pressures from the pinhole calibration method (Sect. 3.1). The UHP gases help maintain low H₂O vapour (< 10 ppm, verified by dew-point hygrometer measurement), NOₓ (< 1 ppbv) and non-methane hydrocarbons (< 1 ppbv) during experimental runs. Thorough mixing of reaction mixtures within HIRAC was achieved in ≤ 70 s by four vibrationally damped, variable speed circulation fans mounted in pairs at each end of the chamber. The chamber was evacuated to ~0.05 mbar for ~60 min following each experiment using a rotary-pump-backed roots blower (Leybold, trivac D40B and ruvac WAU251) to ensure removal of all reactants/products. Known concentrations of precursors were introduced to the chamber in the vapour phase through a 0.97 L stainless-steel delivery vessel. A combined sampling rate of ~9 sLm from the chamber required a counter flow of synthetic air maintaining the desired pressure and diluting the reactants ((4.5 ± 0.2) × 10⁻⁵ s⁻¹). This was regulated using two Brooks mass flow controllers (N₂ and O₂).

### 2.2 HOₓ detection instrument

Calibrations were conducted using both the University of Leeds aircraft- and HIRAC-based FAGE instruments, brief operational details of which are shown in Table 1. The two FAGE systems were very similar in design except for the inlet length and pinhole size as highlighted in Table 1. The aircraft instrument was used as described in Commane et al. (2010) to validate the alternative HO₂ calibration technique only. The HIRAC-based FAGE instrument has also been described in the literature by Glowacki et al. (2007a), and hence only modifications since publication will be discussed here.

Figure 1 shows the cross-sectional schematic of the HIRAC FAGE instrument. Under typical operating conditions, air was sampled at ~6 sLm through a 1.0 mm diameter pinhole nozzle and passed down the inlet (length 280 mm,
Table 1. FAGE instruments used and their respective inlet designs, laser systems and calibration methods used.

50 mm diameter) into the OH detection axis maintained at low pressure (1.8–3.85 mbar) using a high capacity rotary-backed roots blower pumping system (Leybold, trivac D40B and ruvac WAU251). Using the same pump set, the aircraft instrument was operated with a 420 mm long inlet and a 0.6 mm pinhole. The long inlet was used to draw a sample away from the chamber walls where radical losses become significant (see Sect. 2.1). Both instruments were coupled to the HIRAC chamber using custom-made ISO-K160 flanges, ensuring the pinhole, in both cases, was kept ~ 225 mm from the chamber walls.

Concentrations of HO₂ were measured simultaneously in a second detection axis ~ 300 mm downstream of the OH detection axis. High-purity NO (BOC, N2.5 nitric oxide) was added ~ 20 mm before the HO₂ detection axis into the centre of the FAGE cell in the direction of gas flow through 1/8 in. stainless-steel tubing at a rate of 5 sccm (Brooks 5850S), converting HO₂ to OH.

Recently published material on the conversion of certain RO₂ radicals to OH upon reaction with NO in FAGE detections cells (Fuchs et al., 2011; Whalley et al., 2013) has shown a significant enhancement of the HO₂ signal in the presence of RO₂ derived from certain hydrocarbons. These effects have been thoroughly studied using a range of different hydrocarbons for the HIRAC FAGE apparatus and will be the subject of a further publication. The potential interferences associated with HO₂ measurements in the presence of certain hydrocarbons due to the presence of β-hydroxyperoxy radicals do not apply to either HO₂ calibration method. In addition, any interference from RO₂ radicals produced during the alternative calibration methods was experimentally demonstrated to be negligible under the conditions of these experiments (Winiberg, 2014).

Experiments with the HIRAC FAGE instrument used a new medium pulse repetition frequency (PRF) laser light source (= 200 Hz), with a different light delivery method to the detection cells, compared to that described by Glowacki et al. (2007a). The previously used JDSU Nd:YAG pumped Sirah Cobra Stretch system (PRF = 5 kHz) focussed the frequency-doubled 308 nm output into fibre optic cables (10 m, Oz Optics), which were then attached directly to the FAGE cell arms via collimators (Oz Optics). Using the new Litron Nd:YAG (NANO-TRL-50-250) pumped Lambda Physik (LPD3000) dye laser system (PRF = 200 Hz), the high laser pulse energies were found to burn the ends of the fibre optic cables, and hence direct light delivery was applied using a combination of mirrors, lenses and irises to direct and shape the beam to the OH and HO₂ detection regions, as shown in the top-down schematic of the modified HIRAC FAGE instrument displayed in Fig. 2.

The UV light exiting the dye laser was split with a quartz flat (Fig. 2, Q1) to direct ~ 5 % of the laser light towards the reference cell (where OH was generated continuously from a hot wire filament in water-saturated air), which enabled precise tuning of the laser wavelength to the maxima of the OH Q1 (2) branch (within 98 %). The remaining light was aligned through the OH and HO₂ cells sequentially using a series of 308 nm centred turning optics (M1–M4, CVI Laser...
Optics, Melles Griot). A lens was used (L1, f = 100 mm) in conjunction with an iris (I2), to help transmit the laser beam through both detection cells, avoiding collisions with any internal surfaces. Fluctuations in laser power were accounted for using a linear-response, UV-sensitive photodiode (UDT-555UV, Laser Components UK) at the exit arm of the HO$_2$ detection axis to normalise the LIF signal. Both laser systems provided 5–7 and 2–3 mW of 308 nm light to the OH and HO$_2$ detection axes respectively.

The OH fluorescence was collected orthogonal to the gas flow onto electronically gated Channeltron PhotoMultiplier tubes (CPM, Perkin Elmer, C943P) via a series of imaging lenses and a narrow-bandpass filter (Barr Associates, 308.8 ± 5.0 nm). A spherical concave back reflector was positioned underneath the cell, opposite the detection optics, to optimise light collection onto the CPM. To avoid detector saturation, the CPM was gated (i.e. switched off) for the duration of the laser pulse using a modified gating unit based on the original design by Creasey et al. (1997a). Signals from the CPM were analysed using photon-counting cards (Becker and Hickl PMS–400A).

A new OH scavenger system was installed to help discriminate between OH sampled from the chamber and laser-generated OH in the fluorescence cells due to the higher pulse energies associated with the 200 Hz PRF laser system (1 × 10$^{13}$ compared to 5 × 10$^{12}$ photons pulse$^{-1}$ cm$^{-2}$ at 5 kHz for laser power = 8 mW). A mixture of iso-butane (20 % in N$_2$) was injected ∼40 mm inside the inlet pin-hole into the central flow (Fig. 1), through a 1/8 in. internal-diameter stainless-steel pipe at a rate of ∼20 scm, reacting with the sampled OH before reaching the detection axis. The laser-generated OH was probed within the same laser pulse (12 ns) and hence was not suppressed by the scavenger injection. Multiple photolysis of the same gas sample was avoided as the residence time in the laser pulse cross section (∼0.5 cm$^2$) was calculated at ∼0.4 ms, compared to a laser pulse every 5 ms at 200 Hz PRF (assuming plug flow at a 6 sLm ambient sampling rate). Neither a pressure increase nor attenuation of UV light was detected during the scavenger injection process at this flow rate and dilution.

3 Calibration procedures

3.1 Conventional H$_2$O vapour photolysis calibration

The requisite equation for calibration of FAGE by water vapour photolysis was given as

\[ [\text{OH}] = [\text{HO}_2] = [\text{H}_2\text{O}] \sigma_{\text{H}_2\text{O}, 184.9\text{nm}} \Phi_{\text{OH}} F_{\text{184.9 nm}} \Delta t \]  

(3)

and the principles were outlined above in Sect. 1. A schematic diagram of the H$_2$O vapour photolysis calibration source is presented in Fig. 3, consisting of a square cross-section flow tube (12.7 × 12.7 × 300 mm) through which 40 sLm of humidified air (BOC, BTCA 178) was passed, resulting in a turbulent flow regime (Reynolds number ≥ 4000). The air was humidified by passing a fraction of the total air flow through a deionised water bubbler system, and [H$_2$O] was measured using a dew-point hygrometer (CR4, Buck Research Instrument) prior to the flow tube. The collimated 184.9 nm output of a mercury Pen-Ray lamp (LOT-Oriel, Hg-Ar) was introduced to the end of the main flow tube, photolysing H$_2$O vapour (Reactions R2–R3). The gas output from the flow tube was directed towards the FAGE sampling inlet, where the overfill of the FAGE sample volume from the flow tube stopped the impingement of ambient air. A range of HO$_x$ concentrations were produced by changing both the H$_2$O vapour concentration and the mercury lamp photon flux.

The flux of 184.9 nm light, $F_{\text{184.9 nm}}$, was varied by altering the Hg lamp supply current and was dependent on the specific mercury lamp employed along with the lamp temperature and orientation (Hofzumahaus et al., 1997; Creasey et al., 2000; Dusanter et al., 2008). To this end, determinations of the flux from the specific mercury lamp used in the calibrations described in this work were made in situ for lamp supply currents between 0.2 and 3.0 mA using the N$_2$O actinometry method described in detail in a number of publications (Edwards et al., 2003; Heard and Pilling, 2003; Falloon et al., 2004; Glowacki et al., 2007a; Whalley et al., 2007).
The exposure time of the air to the 184.9 nm light, \( \Delta t \), was calculated as a function of the known velocity of the air and the cross section of the photolysis region.

Various cell conditions and their effect on the sensitivity to \( \text{OH} \) and \( \text{HO}_2 \) have been reported in the literature (Faloona et al., 2004; Martinez et al., 2010; Regelin et al., 2013). Here, instrument sensitivity as a function of internal cell pressure has been determined for the HIRAC FAGE instrument using the 200 Hz PRF laser source only (Table 1). Different internal cell pressures (1.8–3.8 mbar) were achieved by changing the diameter of the FAGE inlet pinhole between 0.5 and 1.0 mm. For the aircraft FAGE instrument, inlet pinhole diameters between 0.3 and 0.6 mm were used giving internal cell pressures between 1.4 and 2.5 mbar.

3.2 Hydrocarbon decay method – OH calibration

Hydrocarbons (0.5–2.0 \( \times 10^{13} \) molecule cm\(^{-3} \)) and the OH precursor, \( \text{tert-Butyl hydroperoxide} \) (TBHP, Sigma Aldrich \( \sim 40 \% \) in \( \text{H}_2\text{O} \), 2.0 \( \times 10^{13} \) molecule cm\(^{-3} \)) were introduced to the chamber before the lamps were switched on, initiating the decay experiment. \( \text{OH} \) was produced directly from the photolysis of TBHP at \( \lambda = 254 \) nm and is, as far as we are aware, the first chamber experiment to use TBHP photolysis as a source of \( \text{NO}_2 \)-free \( \text{OH} \). Upon illumination of the chamber, rapid photolysis led to an instantaneous peak \([\text{OH}] \sim 10^7 \) molecule cm\(^{-3} \) before \( \text{OH} \) decayed away over \(~ 30 \) min as the TBHP was removed by photolysis, whilst \( \text{OH} \) was removed through reaction with TBHP (\( k_{\text{OH}}(296 \text{K}) = (3.58 \pm 0.54) \times 10^{-12} \text{ molecule}^{-1} \text{s}^{-1} \); Baa sandorj et al., 2010) and the selected hydrocarbon. The alternative \( \text{OH} \) calibrations presented here were conducted for the HIRAC-based FAGE instrument operating at 200 Hz PRF only.

Cyclohexane (\( > 99 \% \), Fisher Scientific), \( n \)-pentane (\( > 99 \% \), Fisher Scientific) and \( \text{iso-butene} \) (99 \%, Sigma Aldrich) were employed as the hydrocarbons in this study due to their sufficiently fast and well-known rates of reaction with \( \text{OH} \) to provide a quantifiable decay compared to chamber dilution. The rate coefficient for \( \text{OH} \) with \( \text{iso-butene} \) has been evaluated by IUPAC as \( k_{\text{OH}}(298 \text{K}) = (51 \pm 12) \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{s}^{-1} \) (IUPAC, 2007), and rate coefficients for the reaction of \( \text{OH} \) with cyclohexane and \( n \)-pentane have been reviewed by Calvert et al. (2008) as \( k_{\text{OH}}(298 \text{K}) = (6.97 \pm 1.39) \) and \( (3.96 \pm 0.76) \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{s}^{-1} \) respectively (all quoted to \( \pm 2\sigma \)). Whilst alkanes are known to have a pressure-independent rate coefficient for \( \text{OH} \) reactions, the reactions of \( \text{OH} \) with alkenes occur predominantly by addition, a process which is pressure dependent, with the rate coefficient increasing with pressure up to the high-pressure limit where the addition of \( \text{OH} \) is the rate-determining step (Pilling and Seakins, 1995). A study by Atkinson and Pitts (1975) into the reaction of various small-chain alkenes showed no pressure dependence for propene over 33–133 mbar of argon; therefore the reaction of \( \text{OH} \) with the larger \( \text{iso-butene} \) molecule is presumed to be pressure independent above 133 mbar (Atkinson, 1986; Atkinson et al., 2004). To confirm this, a relative rate study in air was conducted using isoprene as a reference (\( k_{\text{OH}}(298 \text{K}) = (1.00 \pm 0.14) \times 10^{-10} \text{ cm}^3 \text{ molecule}^{-1} \text{s}^{-1} \), IUPAC, 2007). Both direct and relative rate studies have shown that the reaction of isoprene and \( \text{OH} \) is at the high-pressure limit above 100 Torr (Campuzano-Jost et al., 2004; Park et al., 2004; Singh and Li, 2007). Figure 4 shows that there is no significant pressure dependence in \( k_{\text{OH}} \) for \( \text{OH} + \text{iso-butene} \) over the 250–1000 mbar pressure range within the uncertainty of the experiment (\( \sim 25 \%, \pm 2\sigma \)) and that the measured rate coefficient, \( k_{\text{OH}}(298 \text{K}) = (4.87 \pm 0.83) \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{s}^{-1} \), is in good agreement with the literature values (5.07 \( \pm 0.51 \) \( \times 10^{-11} \) cm\(^3 \) molecule\(^{-1} \) s\(^{-1} \) for IUPAC; Atkinson, 2003; IUPAC, 2007).

The hydrocarbon decay method relies on the loss of hydrocarbon being solely due to reaction with \( \text{OH} \), and hence the effects of \( \text{O}_3 \) and \( \text{NO}_3 \) as reagents must be considered as both are important in the oxidation of alkenes (Atkinson, 1994). Before photolysis, \( \text{O}_3 \) and \( \text{NO}_3 \) were measured to be around the instrumental detection limits (0.5 and 0.050 ppb at 60 s averaging respectively) using commercial analysers (details given in Sect. 2.1). Upon photolysis a slow increase in \( \text{O}_3 \) and \( \text{NO}_2 \) was observed, to a maximum of \(~ 40 \) and \(~ 20 \) ppbv respectively. The \([\text{NO}_3] \) upper limit was estimated at \(~ 0.32 \) pptv using a simple steady-state approximation, where \( \text{NO}_3 \) production was controlled purely by...
O₃ + NO₂ → NO₃ (Atkinson et al., 2004) and loss by photolysis (j(NO₂) = 1.93 ± 0.10; Glowacki et al., 2007a). Under these conditions it was estimated that > 98% of the loss of iso-butene would be due to OH and not O₃ or NO₃ where kO₃ = (1.13 ± 0.33) × 10⁻¹⁷ cm³ molecule⁻¹ s⁻¹ and kNO₂ = (3.4 ± 1.0) × 10⁻¹³ cm³ molecule⁻¹ s⁻¹ (Calvert et al., 2000).

3.3 Formaldehyde photolysis – HO₂ calibration

Formaldehyde was produced by direct heating of paraformaldehyde powder in a glass finger (Sigma Aldrich, 99%) and was introduced in a flow of nitrogen into the chamber at concentrations ~2 × 10¹³ molecule cm⁻³ (determined manometrically). The chamber was irradiated (lamps: Philips TL40W/12 RS), resulting in an almost instantaneous HO₂ signal. Once an approximately steady-state HO₂ concentration was achieved, the photolysis lamps were turned off and the decay of HO₂ was monitored by FAGE for ~120 s until near-background signals levels were reached. The measurement of HO₂ decays was repeated up to five times before the laser wavelength was scanned to the offline position. Therefore five individual CH₂O determinations could be achieved from one chamber fill, with the limiting factor being the increased complexity of the reaction mixture after repeated photolysis cycles. After five decays, the analysis often exhibited evidence of secondary chemistry starting to distort the HO₂ signal profiles, showing non-linearity in second-order plots. The absence of OH in these experiments was confirmed by simultaneous measurement of OH in the OH fluorescence cell, giving signals below the detection limit (1.6 × 10⁹ molecule cm⁻³ for 60 s averaging for the 200 Hz PRF laser system).

Formaldehyde concentrations were kept low (< 3 × 10¹³ molecule cm⁻³) to avoid removal of HO₂ via reaction with HCHO, ensuring that the loss of HO₂ occurs predominately via self-reaction and wall loss (Sect. 4.2). The HO₂ calibrations were conducted for the HIRAC-based FAGE instrument operating at 200 Hz PRF and the aircraft-based FAGE instrument operating at 5 kHz PRF. The chamber mixing fans were used for the majority of calibration data sets discussed here, representative of a typical experimental homogeneous gas mixture. A series of experiments were conducted without the mixing fans to probe the HO₂ recombination and wall-loss kinetics using the aircraft-based FAGE instrument, and these are discussed in greater detail in Sects. 4.2 and 5.3.

4 Data analysis

4.1 Hydrocarbon decay

Figure 5 shows the hydrocarbon decay for iso-butene at 750 mbar and 294 K measured by GC-FID and FTIR. Using the Guggenheim method (Guggenheim, 1926; Bloss et al., 2004) the pseudo-first-order rate coefficient (k') for the hydrocarbon removal was calculated using Eq. (3):

\[ k' = \frac{\ln ([HC]_1/ [HC]_2)}{(t_2 - t_1)}, \]  

where [HC]₁ and [HC]₂ are the concentrations of the hydrocarbon at time t₁ and t₂ respectively. The mean [OH] between t₁ and t₂ was calculated using Eq. (5):

\[ [OH] = \frac{(k' - k_{Dil})}{k_{OH}}, \]  

where k_{Dil} is the dilution rate of the measured [HC] due to continuous sampling from instrumentation (e.g. FAGE). Bloss et al. (2004) found the Guggenheim method to be most effective when smoothing the inferred [OH] over five [HC] measurements (i.e. consider 10 measurements taken at times t₁ − t₁₀; [OH] at t₅ would take [HC]₁ and [HC]₅, [OH] at t₆ would take [HC]₂ and [HC]₆ etc.). Due to the short experiment time (20–30 min) and the 2–6 min time resolution on the GC measurements, this smoothing was not possible. For iso-butene, FTIR measurements were taken every 30 s, and these were typically found to be in excellent agreement with the GC-FID-measured HC decays, as shown in Fig. 5. However, measurement of small changes in the [HC], due to low steady-state [OH] in the chamber (~5 × 10⁹ molecule cm⁻³), led to large point-to-point variation in the inferred [OH], even after the smoothing was applied. A solution was found by fitting the hydrocarbon decay data with an empirical exponential function of the form...
TBHP was used to produce in HIRAC at 1000 mbar and 293 K where photolysis of probe laser at 308 nm, as described by Reactions (R5)–(R7).

The measured un-normalised OH fluorescence signal indicating a two-photon photolysis-probe process from the OH photolysis. The measured un-normalised OH fluorescence signal following lamp photolysis of OH at $t \approx -500$ s, and the photolysis lamps were switched on at $t = 0$ s. The OH inferred from the HC decay method is also displayed in (b). Dashed line at $y = 0$ given for clarity.

$y = A \times e^{(-x/t_1)} + y_0$ as shown in Fig. 5, which allowed the accurate calculation of [HC] at the same time resolution as the FAGE instrument (20 s averaged). A negligible difference between inferred [OH] determined using the FTIR or GC-FID data was observed, and hence only GC-FID-measured hydrocarbon decays were used for direct comparison with n-pentane and cyclohexane.

Displayed in Fig. 6 is a typical [OH] profile for the photo-oxidation of n-pentane ($2.1 \times 10^{13}$ molecule cm$^{-3}$) in HIRAC at 1000 mbar and 293 K where photolysis of TBHP was used to produce $\sim 1.3 \times 10^7$ molecule cm$^{-3}$ OH at $t = 0$. The OH was measured directly using the HIRAC FAGE instrument with the Litron Nd:YAG pumped dye laser light source, operating at 200 Hz PRF. Upon introduction of TBHP ($3.2 \times 10^{13}$ molecule cm$^{-3}$) to the dark chamber at $t \approx -500$ s, an OH signal equivalent to $\sim 2.5 \times 10^6$ molecule cm$^{-3}$ was observed, and was typically < 25% of the total detected OH signal following lamp photolysis. The measured un-normalised OH fluorescence signal was observed to increase quadratically with laser power, suggesting a two-photon photolysis-probe process from the OH probe laser at 308 nm, as described by Reactions (R5)–(R7).

$$\text{TBHP} + \text{hv} \rightarrow \text{OH} + \text{products}, \quad (R5)$$

$$\text{OH} + \text{hv} \rightarrow \text{OH} \times , \quad (R6)$$

$$\text{OH} \times \rightarrow \text{OH} \times + \text{hv} \times \text{LIF}. \quad (R7)$$

This phenomenon was not observed during a brief test of the HIRAC FAGE instrument with a 5 kHz PRF laser system (JDSS Nd:YAG pumped Sirah Cobra Stretch dye laser, as in Glowacki et al., 2007a, and Malkin et al., 2010), most likely due to much lower laser pulse energies for the 5 kHz system (1.6 µJ pulse$^{-1}$ compared to 40 µJ pulse$^{-1}$ at 200 Hz PRF). Using the scavenger injection system (Sect. 2.2), the decay of the TBHP could be accurately described (compared to simultaneous FTIR measurements) characterising the interference signal. At a time defined by the user, the iso-butane scavenger (20% in N$_2$) was injected into the FAGE cell for $\sim 90$ s at $\sim 20$ sccm. Before the chamber photolysis lamps were initiated, the OH interference signal was measured with the scavenger off and on, and the difference in signal was observed to be negligible (within the uncertainty of the measurement). The OH interference profile during the hydrocarbon decay was characterised and accounted for using 3–4 scavenger injections per experiment. An empirical fit to the averaged signals was used to correct the measured OH signal from TBHP laser photolysis over time, shown here in Fig. 6b compared to the inferred [OH] from the GC-FID. The type of fitting parameter (e.g. linear or exponential) was judged depending on the quality of data.

The calibration procedure was completed by plotting the OH signals, normalised for laser power, measured by FAGE as a function of the calculated OH concentrations from the hydrocarbon decays producing a calibration plot with $C_{OH}$ in units of counts cm$^{-2}$ s$^{-1}$ molecule$^{-1}$, as the gradient. A typical calibration plot is shown in Fig. 7 – produced using the decay of cyclohexane at 1000 mbar chamber pressure (see caption for detailed operating conditions). Uncertainties in $C_{OH}$ are quoted to $\pm 2 \sigma$, and error bars represent the standard error, and hence precision, of the measured $S_{OH}$ to $\pm \sigma$. Error bars were kept at $\pm 1 \sigma$ as this represented the precision used in the analysis procedure.

### 4.2 Formaldehyde photolysis

Calibration of the HO$_2$ detection cell required only the generation of HO$_2$ radicals in the HIRAC chamber, and a time-dependent measurement of their subsequent recombination using the FAGE instrument once the photolysis lamps were extinguished. Upon photolysis in air (lamps: Philips TL40W/12 RS), HCHO produced H + HCO and H$_2$+ CO (Reaction R9) in approximately a 60 : 40 ratio (Reactions R8, R9). Under the conditions in HIRAC, HCO reacted with O$_2$ to give HO$_2$ + CO (Reaction R10) and the H atom produced in Reaction (R8) reacted with O$_2$ to give HO$_2$ (Reaction R11). The loss of HO$_2$ was characterised by the competing bimolecular and termolecular self-reactions (Reactions R12 + R13) and a first-order wall-loss parameter (Reaction R14):
Figure 7. Calibration from the hydrocarbon decay method for cyclohexane at 1000 mbar and 293 K chamber pressure using the HIRAC FAGE instrument with the 200 Hz PRF laser system; inlet pressure = (3.81 ± 0.02) mbar; laser power = (7.0 ± 0.5) mW; [H₂O] vapor < 10 ppmv. Extrapolated calibration from the H₂O photolysis calibration technique for inlet pressure = (3.79 ± 0.02) mbar, laser power = (6.0 ± 0.5) mW, [H₂O] vapor < (3900 ± 20) ppmv and [OH] = (0.5–1.5) × 10⁹ molecule cm⁻³. Both fits are weighted to errors in the x and y axes and error bars are representative of the standard error in the measurement to ±2σ. Uncertainties quoted for the slope and intercept represent the precision of the calibration processes to ±2σ.

HCHO + hv → H + HCO or H₂ + CO (R8)
HCO + O₂ → HO₂ + CO (R9)
H + O₂ + M → HO₂ + M (R10)
HO₂ + HO₂ → H₂O₂ + O₂ (R11)
HO₂ + HO₂ + M → H₂O₂ + O₂ + M (R12)
HO₂ → Loss. (R13)

Therefore the rate of loss of HO₂ is given by:

\[
\frac{d[\text{HO}_2]}{dt} = -\left(k_{\text{loss}}[\text{HO}_2] + k_{\text{HO}_2+\text{HO}_2}[\text{HO}_2]^2\right), \quad (6)
\]

where \(k_{\text{HO}_2+\text{HO}_2}\) is the HO₂ recombination rate coefficient; the sum of the pressure-independent (Reaction R12) and pressure-dependent (Reaction R13) rate coefficients as determined by IUPAC (2007). Solving analytically for [HO₂], at a given time, \(t\), integration of Eq. (5) becomes

\[
\frac{1}{[\text{HO}_2]} = \left(\frac{1}{[\text{HO}_2]_0} + \frac{2 \cdot k_{\text{HO}_2+\text{HO}_2}}{k_{\text{loss}}}\right) \times e^{(k_{\text{loss}}t)} - \left(\frac{2 \cdot k_{\text{HO}_2+\text{HO}_2}}{k_{\text{loss}}}\right), \quad (7)
\]

The [HO₂] in Eq. (6) is unknown but is related to the normalised HO₂ signals measured by FAGE, \(S_{\text{HO}_2}\), and the instrument sensitivity to HO₂, \(C_{\text{HO}_2}\), and therefore

\[
(S_{\text{HO}_2})_t = \left(\frac{1}{(S_{\text{HO}_2})_0} + \frac{2 \cdot k_{\text{HO}_2+\text{HO}_2}}{k_{\text{loss}} \cdot C_{\text{HO}_2}}\right) \times e^{(k_{\text{loss}}t)} - \left(\frac{2 \cdot k_{\text{HO}_2+\text{HO}_2}}{k_{\text{loss}} \cdot C_{\text{HO}_2}}\right)^{-1}, \quad (8)
\]

where \((S_{\text{HO}_2})_t\) and \((S_{\text{HO}_2})_0\) are the HO₂ signal at time \(t\) and \(t = 0\) respectively.

The measured decay of \(S_{\text{HO}_2}\) using FAGE and the fit described by Eq. (7) are displayed in Fig. 8a for a typical experiment (aircraft FAGE instrument (5 kHz PRF), 1000 mbar, 298 K, < 10 ppm [H₂O], mixing fans on). Both \(k_{\text{loss}}\) and \(C_{\text{HO}_2}\) were determined by data fitting the \(S_{\text{HO}_2}\) decay using Eq. (7) with a Levenberg–Marquardt non-linear least-squares algorithm, fixing the initial signal and \(k_{\text{HO}_2+\text{HO}_2}\). The first ~100 s of data were used, ensuring analysis after an almost complete decay of \(S_{\text{HO}_2}\). Fitting was improved by the inclusion of upper and lower bounds of ±10% for the \((S_{\text{HO}_2})_0\) into the fitting routine, which accounted for the uncertainty in the determination of \((S_{\text{HO}_2})_0\) (see Sect. 5.4.3).

For the experimental 350–1000 mbar pressure range at 0% H₂O vapour, \(k_{\text{HO}_2+\text{HO}_2}\) was determined between (2.00–2.85) × 10⁻¹² cm mole⁻¹ s⁻¹, according to the recommendation given by IUPAC (2007). A calibration was conducted at [H₂O]vap = 7500 ppmv, to validate the calibration method at high water vapour concentrations, representative of the conventional H₂O vapour photolysis method. The \(k_{\text{HO}_2+\text{HO}_2}\) therefore included a correction for the H₂O-H₂O vapour chaperone effect (Stone and Rowley, 2005) in accordance with the IUPAC recommendation (Atkinson et al., 2004). The wall-loss rate, \(k_{\text{loss}}\), was dependent on daily chamber conditions and was therefore determined as part of the fitting procedure along with \(C_{\text{HO}_2}\), typically between 0.032 and 0.073 s⁻¹. Variations in the wall-loss rates have implications for the uncertainty in the determination of \((S_{\text{HO}_2})_0\) (see Sect. 5.4.3).

5 Results and discussion

All results presented here were taken using the HIRAC FAGE instrument using Litron Nd:YAG pumped dye laser light source operating at 200 Hz PRF, unless otherwise stated. Tabulated data from the alternative calibration methods are displayed in the Supplement (Tables S1 and S2). All uncertainties displayed are quoted to ±2σ and all regressions shown are empirical, unless otherwise stated.

5.1 Conventional H₂O vapour photolysis calibration

5.1.1 C_{OH} and C_{HO2} as a function of internal cell pressure

The FAGE instrument sensitivity to OH (Fig. 9, HIRAC FAGE only) and HO₂ (Fig. 10, top) was determined as a
Figure 8. Normalised $S_{\text{HO}_2}$ decay for the HCHO photolysis calibration method at 1000 mbar chamber pressure using the aircraft FAGE instrument (5 kHz PRF laser system) conducted with the HIRAC chamber mixing fans on (a) and off (b); inlet pressure = $(2.53 \pm 0.02)$ mbar; laser power = $(8.25 \pm 0.25)$ mW. Data in (a) were fitted with Eq. (7) to give $C_{\text{HO}_2}$ where $A = S_{\text{HO}_2}0$, $k_b = k_{\text{HO}_2} + k_{\text{HO}_2}$, $c = C_{\text{HO}_2}$, $k_a = k_{\text{loss}}$ and $z = \text{offset}$, with uncertainties quoted to $\pm 1\sigma$. Parameters without quoted error were fixed.

function of pressure using the H$_2$O vapour photolysis calibration method over the inlet pressure range of 1.8–3.8 mbar. Figures 9 and 10 display the H$_2$O calibration data compared to those from the respective alternative calibration methods, the results for which are discussed in Sects. 5.2 and 5.3; error bars in both figures are representative of the total uncertainty in the calibration (Sect. 5.4 for details). Constant laser power and [H$_2$O] were maintained throughout the calibration process (8 ± 1 mW and 4500 ± 600 ppmv respectively).

The linear regressions were used to describe the sensitivity as a function of fluorescence cell pressure for experiments conducted in HIRAC, and are a valid description of the data inside the 1.8–3.8 mbar pressure range only. The $C_{\text{OH}}$ and $C_{\text{HO}_2}$ data sets shown here were not conducted at the same time, but 6 months apart. This was due to the chronological order of the development of the alternative calibration techniques, during which time the FAGE pump set was serviced, increasing the pumping capacity and generally lowering the internal cell pressures for each pinhole in the $C_{\text{OH}}$ determination.

The fit displayed a greater increase in $C_{\text{HO}_2}$ as a function of pressure compared to $C_{\text{OH}}$, where $\Delta C_{\text{OH}} = (17 \pm 11)\%$ and $\Delta C_{\text{HO}_2} = (31.6 \pm 4.4)\%$ increase between 1.3 and 3.8 mbar. Altering the pinhole diameter could change the flow dynamics inside the instrument, reducing NO mixing efficiency, and therefore HO$_2$ conversion efficiency, before the HO$_2$ cell. The decrease in $C_{\text{HO}_2}$ at lower pressure has been reproduced in a more recent calibration of the HO$_2$ cell using the 5 kHz PRF laser source (slope = $(5.14 \pm 0.46) \times 10^{-9}$ counts cm$^3$ molecule$^{-1}$ s$^{-1}$ mW$^{-1}$ mbar$^{-1}$), suggesting the process was not affected by changes in laser pulse energy.

The experimental parameters controlling the instrument sensitivity, $C_{\text{OH}}$, which are dependent upon pressure, are the OH concentration in the laser-excitation region, [OH]$_{\text{cell}}$; the fluorescence quantum yield following laser excitation to the OH A$^2\Sigma^+ (v' = 0)$ excited state, $\varphi_{\text{fl}}$; and the fraction of the fluorescence decay which falls within the integrating gate of the photon counter, $f_{\text{gate}}$ (Creasey et al., 1997b; Falloona et al., 2004). The OH concentration in the cell held at total density $[M]$ and the fluorescence quantum yield are given by
Eqs. (8) and (9):

\[
[\text{OH}]_{\text{cell}} = \chi [M],
\tag{9}
\]

\[
\psi_{\text{ff}} = \frac{A}{(A + k_q[M])},
\tag{10}
\]

where \( \chi \) is the mixing ratio of OH impinging at the pinhole (assuming no losses at the pinhole), \( A \) is the inverse of the radiative lifetime of OH and \( k_q \) is the rate coefficient for quenching of the excited \( A^2 \Sigma^+ \) (\( v' = 0 \)) (averaged appropriately over all quenching species). Assuming that \( f_{\text{gate}} = 1 \), then the overall pressure-dependent term for instrument sensitivity to OH can be described as the product of Eqs. (8) and (9), shown here in Eq. (10):

\[
\psi \chi [\text{OH}]_{\text{cell}} \times \Phi_{\text{ff}} = \frac{[M]A}{(A + k_q[M])}.
\tag{11}
\]

When \([M] \rightarrow 0\), the product becomes \( \chi [M] \), and \( C_{\text{OH}} \) is directly proportional to pressure ([M]). At higher pressures when \( k_q[M] \gg A \) (at 18 mbar the ratio is \( \sim 10 \)), the product becomes \( \sim \chi A/k_q \) and \( C_{\text{OH}} \) is independent of \([M]\), and thus depends only on the mixing ratio of OH.

However, FAGE is an on-resonance technique, and therefore it is not possible to achieve the limit \( f_{\text{gate}} = 1 \), because it is necessary to gate off the CPM during the laser pulse in order to avoid saturation of the detector. Thus, in these experiments \( f_{\text{gate}} \) was always < 1, and depended non-linearly on pressure because the photon-counting gate remained the same whilst the fraction of the total fluorescence collected within this gate \( (f_{\text{gate}}) \) changed as a result of changes in the total fluorescence lifetime of the excited-state OH radicals. Thus the effective area of integration under the fluorescence decay curve reduced with increasing pressure such that \( f_{\text{gate}} \) reduced non-linearly as pressure increased. For the conditions used in these experiments \( f_{\text{gate}} = 0.79–0.63 \) (between 1.3 and 3.8 mbar). Hence the observation that \( C_{\text{OH}} \) increased linearly over pressures between 1.3 and 3.8 mbar in this study is consistent with the expected behaviour based purely on the balance between OH number density and the total fluorescence collected.

The inherent complexity that results from the multiple factors which control the sensitivity of FAGE instruments, and which also change with a variety of conditions (i.e. pressure, [H2O], laser power) and instrumental factors (e.g. time take for CPM to reach maximum gain), require that FAGE instruments are frequently and carefully calibrated.

Additional investigations into the FAGE instrument sensitivity to OH as a function of [H2O]vap and laser power are discussed in detail in the Supplement. The change in instrument sensitivity over [H2O] between 200 and 4500 ppmv was observed to be within the uncertainty of the calibration (35 % at 2σ) and was therefore considered negligible. For this reason no correction for sensitivity to [H2O] was applied to the date taken in the alternative calibration method where [H2O] < 10 ppmv.

5.2 Hydrocarbon decay calibration

Figure 7 shows a direct comparison of analysed data from the decay of cyclohexane and H2O vapour calibration method at \( \sim 3.80 \) mbar internal cell pressure (equivalent to 1000 mbar in HRAC) using the 1.0 mm inlet pinhole and \( \sim 7 \) mW laser power. The \( C_{\text{OH}} \) was determined as \((2.13 \pm 0.52) \times 10^{-8} \) counts s\(^{-1}\) molecule\(^{-1}\) cm\(^3\) mW\(^{-1}\), within error of the traditional H2O vapour photolysis calibration (2σ) at the same pressure \((2.62 \pm 0.91) \times 10^{-8} \) counts s\(^{-1}\) molecule\(^{-1}\) cm\(^3\) mW\(^{-1}\)). Error bars are representative of the total uncertainty at ±1σ. Additional example calibration plots for each hydrocarbon.
studied are included in the Supplement. Displayed in Fig. 9 is \( C_{\text{OH}} \) as a function of internal cell pressure using the HC decay calibration method, determined for iso-butene, cyclohexane and \( n \)-pentane. The HC decay calibration method was observed to be in agreement with the \( \text{H}_2\text{O} \) vapour photolysis calibration. The average of the ratio of calibration factors (conventional : alternative) was calculated for each alternative calibration point across the entire pressure range, \( C_{\text{OH(conv)/OH(alt)}} = 1.19 \pm 0.26 \), where \( C_{\text{OH(alt)}} \) was determined from the fit to the \( \text{H}_2\text{O} \) photolysis data.

A large variability in the \( C_{\text{OH}} \) determined using the iso-butene decay was observed, with larger uncertainties associated with this calibration compared to cyclohexane and \( n \)-pentane, and the reason for this remains unclear. On average, the measured OH signals were closer to the detection limit of the FAGE instrument when using iso-butene. Initial concentrations of each of the hydrocarbons were \( 2.5 \times 10^{13} \text{ molecule cm}^{-3} \), and hence a lower OH steady-state concentration is expected when iso-butene is present as the \( k_{\text{OH}} \) is an order of magnitude higher than those for \( n \)-pentane and cyclohexane. As \( S_{\text{OH}} \) approaches 0 counts s\(^{-1}\) mW\(^{-1}\), the \( S_{\text{OH}} \) measurement becomes increasingly imprecise, and thus the uncertainty in the fitting of the calibration plot increases.

A general under-prediction of \( C_{\text{OH}} \), compared to the \( \text{H}_2\text{O} \) vapour photolysis method, was observed when calculated using the decay of cyclohexane, \( C_{\text{OH(conv)/OH(Chex)}} = 1.52 \pm 0.44 \). The exact reason is unknown. Evaluation of the HC decay data with the \( k_{\text{OH}} \) adjusted at the upper limit of uncertainty recommended by Calvert et al. (2008) (25\% \( \sigma \), \( k_{\text{OH}} = 8.04 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \)) brings the two data sets into better agreement, \( C_{\text{OH(conv)/OH(Chex)}} = 1.21 \pm 0.22 \). The cyclohexane measurements were also affected to a greater extent by the chamber dilution due to the slower rate of reaction with OH, which contributed to 25–30\% of the total cyclohexane decay rate directly after the photolysis lamps were initiated, compared to 5–10\% for the iso-butene experiments. Correcting the cyclohexane data for a hypothetically enhanced chamber dilution could explain the lower sensitivity measurements (as the decay increases, \( [\text{OH}]_{\text{inf}} \) increases), however the dilution rate was confirmed prior to photolysis of TBHP in each experiment.

5.3 Formaldehyde photolysis calibration

Figure 10a shows the instrument sensitivity to \( \text{HO}_2 \), \( C_{\text{HO}_2} \), as a function of internal cell pressure for the newly developed formaldehyde photolysis calibration technique for the HIRAC FAGE instrument. Each data point corresponds to the average of up to five \( \text{HO}_2 \) decay traces (Fig. 8a), and the error bars are representative of the total calibration \( \sigma \) uncertainty (Sect. 5.4). All calibrations were completed over a 4–8 mW laser power range. The alternative calibration was observed to be in good agreement with the conventional \( \text{H}_2\text{O} \) vapour photolysis calibration technique over the operating internal cell pressure range of 1.8–3.8 mbar \( (\text{HO}_2(\text{conv})/\text{HO}_2(\text{alt}) = 0.96 \pm 0.09) \) for the Litron-based FAGE system.

The kinetics of the \( \text{HO}_2 \) decay due to recombination and first-order wall loss (Eq. 7) were confirmed by studying the \( \text{HO}_2 \) decay profile with the chamber mixing fans on and off using the University of Leeds aircraft-based FAGE instrument. With the mixing fans off, the decay was accurately described by the recombination kinetics only (Fig. 8b), giving \( C_{\text{HO}_2} \) values within error of the fans on experiments, as shown in Fig. 10b. Good agreement between the conventional and alternative calibration methods was also observed across the 1.42–2.48 mbar internal cell pressure range, and the overall correlation between conventional and alternative calibration methods was calculated as \( C_{\text{HO}_2(\text{conv})/\text{HO}_2(\text{alt}) = 1.07 \pm 0.09 \) for the high-frequency aircraft-based FAGE instrument.

5.4 Calibration uncertainties

The overall uncertainty associated with the calibration methods presented here was calculated using the sum in quadrature of the accuracy and the precision terms of the calibration. The accuracy term accounted for any systematic uncertainty in the calculation of \( [\text{HO}_2] \) for each calibration method, signal normalisation etc., and these are displayed in Table 2. The precision of the calibrations was defined as the random errors associated with each method. All uncertainties are quoted as 2\( \sigma \).

5.4.1 \( \text{H}_2\text{O} \) photolysis calibration

The total uncertainty in the \( \text{H}_2\text{O} \) photolysis calibration method was estimated to be \( \sim 36\% \). The accuracy was defined by the uncertainty associated with each term of Eq. (1) in the determination of \( [\text{HO}_3] \) and was estimated to be \( \sim 35\% \). The largest contribution to the accuracy of this calibration method came from the determination of the calibration source flux, \( F_{184.9 \text{nm}} \), with a total uncertainty of 32\%. The product of the flux and the irradiation time from Eq. (1), \( F_{184.9 \text{nm}} \times \Delta t \), was determined using \( \text{N}_2\text{O} \) actinometry which relied on the detection of trace levels of NO (0.5–3 ppbv, Sect. 2.1) followed by evaluation of the measurements using four rate constants each with \( \sim 20\% \) uncertainty. Although the actinometric method gives a direct determination of the product \( F_{184.9 \text{nm}} \times \Delta t \), in order to calculate \([\text{OH}] \) from Eq. (1) any differences between the total volumetric flow rate during the actinometry experiment and the OH calibration needs to be accounted for as they change \( \Delta t \). It is therefore necessary to account for the uncertainty in \( \Delta t \), which was determined to be \( \sim 2\% \) using the uncertainty in the flow rates from the mass flow controllers (\( \sim 1\% \)). For the remainder of the terms in Eq. (1) their contributions to the accuracy in the \( \text{H}_2\text{O} \) photolysis calibration method were
Table 2. The systematic uncertainties to 2σ in the various parameters that determine the accuracy in the OH and HO\textsubscript{2} calibration factors for all three calibration methods. Total accuracy is taken as the sum in quadrature of the individual uncertainties. The Online position error is the approximate error in the maximum line intensity that is achieved when positioning the laser wavelength at the centre of the OH transition.

as follows: $\sigma_{\text{H}_2\text{O}}$ was taken from Cantrell et al. (1997), with a reported total error of ±6%; the error in $[\text{H}_2\text{O}]$ was taken from the hygrometer instrumental uncertainty (±10%); and laser power was defined by the laser power meter (Molelectron Powermax 500A ±0.25 mW).

The precision was typically between 4 and 10 % for the flow tube calibration process and was taken from the standard error in the error-weighted fit of the calibration plot. The error bars were representative of the standard deviation in the $S$0\textsubscript{H} and $[\text{HO}_{x}]$ for the $x$ and $y$ axes respectively. The flux output of the calibration source, hygrometer and CPM measurements were observed to have good point-to-point stability and therefore low standard deviations.

5.4.2 Hydrocarbon decay calibration

The accuracy of the hydrocarbon decay method was estimated to be better than that of the flow tube method (28 % compared to 35 %). However, due to the large variation in the random errors that defined the precision of the experiment, the total uncertainty for the HC decay method was larger than the flow tube calibration method, with the total uncertainty estimated at ~45 %.

The accuracy in the calibration was intrinsic to the hydrocarbon used, being dependent on the uncertainty in $k_{OH}$ and $k_{Dil}$. The largest uncertainty was in $k_{OH}$, taken from data reviews from the Calvert series or IUPAC recommendations: $n$-pentane, ±20 % (Calvert et al., 2008); cyclohexane, ±20 % (Calvert et al., 2008); and iso-butene, ±25 % (IUPAC, 2007). Uncertainty in $k_{Dil}$ was calculated from repeated measurements of chamber dilution for each of the hydrocarbons, and induced errors in GC-FID calibration (4 %). The precision of the experiments for both $n$-pentane and cyclohexane was between 10 and 25 %, whereas iso-butene showed much greater variation of between 13 and 69 %; possible reasons for this have been discussed in Sect. 5.2.

5.4.3 Formaldehyde photolysis calibration

The total uncertainty for the HCHO photolysis calibration method has been estimated at ~46 %, which is 10 % greater than the conventional calibration method. The accuracy of the HCHO photolysis method was estimated as ~41 %; the largest contribution to this deriving from the uncertainty was in the HO\textsubscript{2} recombination rate constant (35 %), taken from the IUPAC recommendation (IUPAC, 2007). Determining the accurate initial $S_{\text{HO}2}$ (i.e. $S_{\text{HO}2}$ at $t_0$) is hard as HO\textsubscript{2} does not fully reach steady state before the photolysis lamps are switched off; therefore there is a certain amount of subjective choice in the value of $S(\text{HO}_2)t_0$, and hence the uncertainty in the initial $S_{\text{HO}2}$ was based on the standard deviation of the mean “steady-state” HO\textsubscript{2} signal, which gives an estimation of the 1 s point-to-point variability for a chosen $t_0$ (~20 %).

The error associated with the precision of the experiment was taken from the error propagation of the standard error terms from the Levenberg–Marquardt iterative fitting procedure for Eq. (9) and Fig. 8. This includes both the error in the C\textsubscript{H}0\textsubscript{2} and $k_{\text{loss}}$ parameters. The precision for this method was in line with the conventional flow tube calibration between 10 and 20 %.

6 Conclusions and outlook

The first pressure-dependent calibrations of a FAGE instrument for both OH and HO\textsubscript{2} have been successfully conducted using the HIRAC chamber. Previous pressure-dependent aircraft measurements had been extracted by assuming that the calibration factor could be determined by simply calibrating at the required internal FAGE cell pressure. Assumptions were therefore made that variations in radical losses on the inlet and the nature of the expansion caused by the varying pressure differential inside and outside the FAGE cell were insignificant. The results displayed in Figs. 9 and 10 validate the conventional calibration method with the alternative hydrocarbon decay and HCHO photolysis methods over a range of internal FAGE cell pressures. It should be emphasised that,
strictly speaking, this validation applies only to these particular FAGE instruments, but this work suggests that the agreement between the different calibration techniques will translate to FAGE instruments of similar designs. As the calibration methods are quite different in principle, they are unlikely to be subject to the same systematic errors. The alternative calibration results presented here have been shown to be well within the combined uncertainty of their respective traditional calibration method, validating the pressure-dependent flow tube calibration technique and improving confidence in FAGE measurements both in the field and in kinetics experiments. Both alternative methods have also shown that calibrations conducted under high [H$_2$O]$_{vap}$ conditions (2000–4500 ppmv) can be applied to measurements at low [H$_2$O]$_{vap}$ (< 15 ppmv).

The hydrocarbon decay method has shown that the FAGE instrument can be calibrated over a range of external pressures using different hydrocarbons. Compared to the conventional calibration method, where [HO$_x$] are generated typically at $> 10^8$ molecule cm$^{-3}$, the hydrocarbon decay method is conducted at a [HO$_x$] relevant to chamber-based experimental measurements ($\sim 10^7$ molecule cm$^{-3}$) and much closer to typical ambient OH concentrations ($\sim 10^6$ molecule cm$^{-3}$).

Currently the total error associated with the hydrocarbon decay method is greater than that of the flow tube method (45 % vs. 36 %). The accuracy or total systematic uncertainty associated with the alternative OH calibration method is lower than that of the flow tube calibration method (28 % vs. 35 %), and hence an improvement in the precision of the experiment could improve the overall uncertainty to be in line with the flow tube method. The primary source of random error arose in the detection of OH close to the detection limit. Increasing the steady-state OH concentration in the chamber would allow easier detection of the hydrocarbon decay compared to chamber dilution, as well as an OH measurement above the detection limit. The steady-state OH concentration could be increased by increasing the 254 nm intensity in the chamber; using new lamps or more lamps; altering the OH precursor, e.g. O$_3$+ alkenes or photolysis of methyl nitrite; or by lowering the initial [HC]. The latter would require a more sensitive hydrocarbon detection technique than GC-FID or FTIR, which are currently available in HIRAC. One such technique is proton transfer mass spectrometry (PTR-MS), which would reduce the uncertainty in the hydrocarbon decay measurements by providing higher-time-resolution measurements and allow for easier simultaneous measurement of multiple hydrocarbons at low concentrations, effectively providing multiple independent estimates of CO$_{OH}$ from a single experiment. Uncertainties in the rate coefficients could also be reduced by a concerted laboratory study including relative rate and direct flash photolysis methods, decreasing the systematic error. With careful experimental design, errors could potentially be reduced to closer to 10 % (Orkin et al., 2010; Carr et al., 2011; Glowacki et al., 2012).

A full range of pressure-dependent calibrations using this method would currently take ~2 days, compared to ~3 h for the flow-tube-based calibration. However, the timescale does not limit the suitability of the method for regular confirmation of CO$_{OH}$ obtained from the flow tube calibration method.

The total uncertainty in the HCHO photolysis method is ~46 % which is 10 % greater than that of the traditional H$_2$O photolysis method. The HCHO photolysis method is quick and reproducible. The time taken to complete the analysis and the errors is comparable with the flow tube technique. An advantage of the HCHO photolysis method is that several runs can be completed in one fill of the chamber, compared to the HC decay method, which requires one fill per experiment (although the proposed use of multiple HC decays will provide multiple estimates of CO$_{OH}$ from a single chamber fill).
