Abstract

Knowledge of the hydrodynamic character of micro-packed beds (μPBs) is critical to understanding pumping power requirements and their performance in various applications, including those where heat and mass transfer are involved. The report here details use of smoothed particle hydrodynamics (SPH) based simulation of fluid flow on models of μPBs derived from X-ray microtomography to predict the hydrodynamic character of the beds as a function of the bed-to-particle diameter ratio over the range $5.2 \leq D/d_p \leq 15.1$. It is shown that the permeability of the μPBs decreases in a non-linear but monotonic manner with this ratio to a plateau beyond $D/d_p \approx 10$ that corresponded to the value predicted by the Ergun equation. This permeability variation was reasonably well-represented by the model of Foumeny (Intnl. J. Heat Mass Transfer, 36, 536, 1993), which was developed using macroscale packed beds of varying bed-to-particle diameter ratios. Five other correlations similarly determined using macroscale beds did not match at all well the SPH results here. The flow field within the μPBs varied in an oscillatory manner with radial position (i.e. channelling occurred at multiple radial positions) due to a similar variation in the porosity. This suggests that use of performance models (e.g. for heat and mass transfer) derived for macroscale beds may not be suitable for μPBs. The SPH-based approach here may well form a suitable basis for predicting such behaviour, however.

Keywords: Porous media; micro-packed bed; pressure drop; permeability; smoothed particle hydrodynamics (SPH); Lagrangian.

1. Introduction

Microfluidics, the science and technology utilised in the processing and manipulation of small amounts of fluids in conduits having dimensions of the order of tens to hundreds of micrometres [1-3], is a fast growing research field with a wide range of potential applications. Its genesis in the early 1990s [4] was in the form of what is now widely termed ‘Micro Total-Analysis-System’ (μTAS) [5, 6], which has since been employed in a range of applications in chemical and biological analysis, including in clinical chemistry [7, 8], medical diagnostics [9, 10], cell biology (e.g. chemotaxis studies) and immunology [11, 12]. Microfluidics is also of relevance beyond μTAS, including in colloid science [13, 14], plant biology [15, 16], and process intensification [17-19]. In the latter, specific applications include micro-chemical engineering technology [20-23], which leads to higher product yields and new reaction pathways not possible in larger scale systems [1, 2, 24, 25], and control of extreme reactions [20, 26-29].

Despite the many potential benefits of microfluidics, the laminar flow that arises from the small dimensions and often simple geometries involved [30, 31] means mixing and, hence, mass and heat transfer are poor [32, 33]; for example: the mixing length, which is the distance that a liquid must travel to become fully intermixed, can be of the order of centimetres or even meters, much greater than is available in typical microfluidic configurations where miniaturization is clearly the desired end-point. One way of addressing the mixing challenge is to use a packed bed, also termed a micro-packed bed (μPB) [34-36]. This approach also facilitates an increase in the surface area-to-volume ratio, which is useful if the particles within the bed are to act as an adsorbent or catalyst [37-40].

Whilst μPBs take many shapes and sizes – see for example the simple, long and narrow T-shaped bed of Jensen and co-workers [41] vs. their more complex, wide but shallow bed elsewhere [36] – they are generally characterised by small bed-to-particle diameter ratios. This small ratio leads to the bed walls having a significant influence on the μPB behaviour compared to the typical macroscale counterparts. The higher porosity near the walls [42, 43] combined with the fact that the wall region constitutes a significant volume of μPBs means significant fluid flow may tend to channel along the walls [44, 45]. Further flow inhomogeneities may also arise in beds constituted from particles of regular shape and size due to confined packing-induced oscillations in the porosity [46, 47]. These factors open up the possibility that the performance of the μPBs (e.g. in mixing) may be less than hoped for. They may also lead to the character of the pressure drop differing from that of typical macroscale packed beds, although opinion appears mixed on this point (see [46, 48] vs. [49, 50] vs. [51]). Given the
pumping power required to overcome pressure drop is a significant issue in the microfluidic context, as is its performance under any circumstances, it is clearly desirable to be able to predict the hydrodynamic character of µPBs.

Given the flow in microfluidic devices is in general laminar, it is anticipated that the relationship between the flow rate through a µPB and the pressure drop, Δp, along its length, L, will be described by Darcy’s Law, which may be expressed as

\[ v = -\frac{k \Delta p}{\mu L} \]  \hspace{1cm} (1)

where \( v \) is the flow rate per unit cross-sectional area, often termed the superficial velocity, \( \mu \) is the fluid viscosity, and \( k \) is the bed permeability, a characteristic related to the nature of the packing. One of the earliest permeability models is due to Ergun [52]

\[ k = \frac{\varepsilon^2 d_p^2}{150(1-\varepsilon)^2} \]  \hspace{1cm} (2)

where \( \varepsilon \) is the bed porosity and \( d_p \) the diameter of the particles that it is made up of. There are many other expressions that have also been developed for the permeability of macroscale packed beds [53, 54], but many will probably not be valid for µPBs because their much smaller bed-to-particle diameter ratio [55], \( D/d_p \), means wall effects are likely to have greater influence. Expressions have, however, been developed for macroscale beds of smaller bed-to-particle diameter ratios. One of the earliest such permeability models is that of Mehta & Hawley [56], who derived the modified-Ergun equation

\[ k = \frac{\varepsilon^2 d_p^2}{150M^2(1-\varepsilon)^2} \]  \hspace{1cm} (3)

where \( M \) is a factor that accounts for the bed-to-particle diameter ratio

\[ M = 1 + \frac{2}{3(1-\varepsilon)} \frac{d_p}{D} \]  \hspace{1cm} (4)

As an alternative, Reichelt [57] proposed the expression

\[ k = \frac{\varepsilon^2 d_p^2}{A_w M^2(1-\varepsilon)^2} \]  \hspace{1cm} (5)

where \( A_w \) is a parameter obtained from fitting the model to experimental data. Others have also used this expression more recently with other experimental data [58, 59], including Eisfeld & Schnitzlein [45], who used 2300 data points from a large number of sources. Foumeny et al. [46] used Eq. (5) with the following expression

\[ A_w = \frac{130}{M^2} \]  \hspace{1cm} (6)
combined with the diameter ratio-dependent porosity expression

\[
\varepsilon = 0.383 + 0.25 \left( \frac{D}{d_p} \right)^{-0.923} \cdot \frac{1}{\sqrt{0.723 \left( \frac{D}{d_p} - 1 \right)}}
\]  

whilst Raichura [60] obtained the following via use of other experimental data

\[
A_w = \frac{103}{M^2} \left( \frac{\varepsilon}{1-\varepsilon} \right)^2 \left[ 6(1-\varepsilon) + \frac{80}{D/d_p} \right]
\]

Cheng [58] proposed the following expression based on a capillary type model

\[
A_w = \frac{1}{M^2} \left[ 185 + 17\left( \frac{\varepsilon}{1-\varepsilon} \right) \left( \frac{D}{D-d_p} \right)^2 \right]
\]

Finally, Di Felice and Gibilaro [61] proposed a model based on a sub-division of a packed bed into two zones to yield

\[
k = \frac{d_p^2 \varepsilon^2 (2.06 - 1.06 (\frac{D/d_p - 1}{D/d_p})^2)}{150(1-\varepsilon)^2}
\]

Whilst all the above expressions attempt to capture the effect of the bed-to-particle diameter ratio, they have all been determined using macroscale data; it is not known how relevant these are for \(\mu\)PBs.

Assessing the validity of the Eqs. (2)-(10) for \(\mu\)PBs could be undertaken through experimental means. However, determination of pressure drop in such systems is challenging due to the relatively small pressure drops and the intricacies of their measurement arising out of the miniaturisation. An alternative is to simulate the flow in models of the pore space of real \(\mu\)PBs. This is done here using smoothed particle hydrodynamics (SPH) [62] on models of \(\mu\)PBs derived from application of a method recently developed by the authors [42, 43] to X-ray tomographic images of real beds of varying bed-to-particle diameter ratios. SPH has been used as it obviates the difficult task of building meshes in the complex three-dimensional (3D) geometry of the \(\mu\)PB pore spaces.

The remainder of the paper is structured as follows. We first detail the governing flow equations and SPH formulation based on these along with the solution algorithm. The model is then benchmarked against the results for flow around a single sphere, which is prototypical of \(\mu\)PBs. Results are then presented for the \(\mu\)PBs and compared with expressions (2)-(10). Consideration of the correlation between the inhomogeneities in the bed porosity and localised flow profiles are also discussed before conclusions are drawn.
2. Model

**Governing equations**

Smoothed particle hydrodynamics (SPH) is based on the Navier–Stokes equations in the Lagrangian frame. For isothermal fluid flow, these equations take the form

\[
\frac{dp}{dt} = -\rho \nabla \cdot \mathbf{v} \quad \text{(11)}
\]

and

\[
\rho \frac{d\mathbf{v}}{dt} = \nabla \cdot \mathbf{\sigma} + \rho \mathbf{g} \quad \text{(12)}
\]

where \( \rho, \mathbf{v} \) and \( \mathbf{\sigma} \) are the fluid density, velocity and stress tensor, respectively, and \( \mathbf{g} \) is the acceleration due to body forces at play such as, for example, gravity. The stress tensor for a Newtonian fluid may be expressed as

\[
\mathbf{\sigma} = -P \mathbf{I} + \mathbf{\tau} \quad \text{(13)}
\]

where \( P \) is the hydrostatic pressure, \( \mathbf{I} \) the unit tensor, and \( \mathbf{\tau} \) the shear stress tensor that may be expressed as

\[
\mathbf{\tau} = -\mu \left( \nabla \mathbf{v} + (\nabla \mathbf{v})^T \right) \quad \text{(14)}
\]

where \( \mu \) is the dynamic viscosity of the fluid.

**SPH formulation**

In SPH [63], the fluid is represented by a discrete set of particles of fixed mass, \( m_i \), that move with the local fluid velocity, \( \mathbf{v}_i \). The velocity and other quantities associated with any particle-\( i \) are interpolated at a position \( \mathbf{r} \) through a summation of contributions from all neighbouring particles weighted by a function, \( W(\mathbf{r}, h) \), with a compact support, \( h \), as illustrated in Figure 1.
Figure 1. An illustration of an SPH weighting function with compact support that is used to evaluate quantities at a point \( r \) such as, for example, the density as shown in Eq. 15.

For example, the density of a particle-\( i \) is given by [64]

\[
\rho_i = \sum_j m_j W(r_{ij}, h)
\]  

(15)

where \( r_{ij} \) is the distance between particles \( i \) and \( j \).

The pressure gradient associated with particle-\( i \) is given by [64, 65]

\[
(\nabla P)_i = \rho_i \sum_j m_j \left( \frac{p_j}{\rho_j^2} + \frac{p_i}{\rho_i^2} \right) \nabla_i W_{ij}
\]

(16)

where \( P_i \) is the pressure associated with particle-\( i \).

Finally, the divergence of the shear stress tensor attached to a particle-\( i \) is given by [66]

\[
(\nabla \cdot \boldsymbol{\tau})_i = \rho_i \sum_j m_j \left( \frac{\tau_j}{\rho_j^2} + \frac{\tau_i}{\rho_i^2} \right) \nabla_i W_{ij}
\]

(17)

where the components of the shear stress tensor, which are derived from Eq. 14, are given by

\[
\tau_{i\alpha\beta} = -\mu \left( \sum_j m_j \frac{v_{ij}^\alpha}{\rho_j} \frac{\partial W_{ij}}{\partial x_i^\beta} + \sum_j m_j \frac{v_{ij}^\beta}{\rho_j} \frac{\partial W_{ij}}{\partial x_i^\alpha} \right)
\]

(18)

where \( v_{ij} = v_i - v_j \).

Combined, these equations lead to the following SPH formulation for the momentum equation

\[
\frac{dv_i}{dt} = -\sum_j m_j \left( \frac{p_j}{\rho_j^2} + \frac{p_i}{\rho_i^2} \right) \nabla_i W_{ij} + \sum_j m_j \left( \frac{\tau_j}{\rho_j^2} + \frac{\tau_i}{\rho_i^2} \right) \nabla_i W_{ij} + \mathbf{g}
\]

(19)

A variety of weighting functions have been used over the past three or more decades [63]. The stability properties of SPH simulations strongly depend on the second derivative of the weighting function [63]. Although the cubic spline is widely employed, the piecewise-linear nature of its second derivative leads to instabilities in SPH simulations involving incompressible viscous creeping flows [63]. This can be avoided by use of higher-order splines [63, 67] such as the quintic spline that is employed here as a compromise between stability and accuracy requirements and efficiency

\[
W(q, h) = \frac{3}{359\pi h^3} \times \begin{cases} 
(3 - q)^5 - 6(2 - q)^5 + 15(1 - q)^5 & 0 \leq q < 1 \\
(3 - q)^5 - 6(2 - q)^5 & 1 \leq q < 2 \\
(3 - q)^5 & 2 \leq q < 3 \\
0 & q > 3
\end{cases}
\]

(20)

where \( q = r/h \).
Solution technique

A two-step predictor-corrector scheme is used to solve the Eq. 19 based on an explicit projection method in which the pressure required to enforce the incompressibility is found via projecting an estimate of the velocity field onto a divergence-free space (i.e. where \( \nabla \cdot \mathbf{v} = 0 \) as indicated by applying the requirement of a constant density on the continuity equation) [68]. Here, the variables are updated from a previous time step, \( t \), to a new time step, \( t+1 \). This is done firstly by estimating the particle positions and velocities using the shear stress and body force terms of the momentum equation in Eq. 19 only (particle indices have been dropped for convenience)

\[
\mathbf{v}^* = \mathbf{v}_t + \left( \frac{1}{\rho} \nabla \cdot \mathbf{t} + \mathbf{g} \right) \Delta t \tag{21}
\]

\[
\mathbf{r}^* = \mathbf{r}_t + \mathbf{v}^* \Delta t \tag{22}
\]

where \( \mathbf{v}_t \) and \( \mathbf{r}_t \) are the particle velocity and position at time \( t \), respectively, and \( \Delta t \) the time step size. The fluid density is then updated by using the intermediate particle positions, \( \mathbf{r}^* \), in Eq. 15.

The new particle velocities are then evaluated by applying a correction to the initial velocity estimates

\[
\mathbf{v}_{t+1} = \mathbf{v}^* + \Delta \mathbf{v}^{**} \tag{23}
\]

where the velocity correction is evaluated using the pressure gradient term of the momentum equation only

\[
\Delta \mathbf{v}^{**} = -\frac{1}{\rho^*} \nabla P_{t+1} \Delta t \tag{24}
\]

The pressure gradient at the new time, \( \nabla P_{t+1} \), is obtained by enforcing incompressibility where \( \nabla \cdot \mathbf{v} = 0 \) as per the continuity equation Eq. 11. Therefore, by combining Eq. 23 and Eq. 24 and taking the divergence, we obtain

\[
\nabla \left( \frac{\mathbf{v}_{t+1} - \mathbf{v}^*}{\Delta t} \right) = -\nabla \left( \frac{1}{\rho^*} \nabla P_{t+1} \right) \tag{25}
\]

Imposing the incompressibility condition at the new time step, \( \nabla \cdot \mathbf{v}_{t+1} = 0 \), leads to the Pressure Poisson Equation (PPE)

\[
\nabla \left( \frac{1}{\rho^*} \nabla P_{t+1} \right) = \frac{\nabla \mathbf{v}^*}{\Delta t} \tag{26}
\]

The left hand side of this equation is discretised using Shao’s approximation for the Laplacian in SPH [69], which is a hybrid of a standard SPH first derivative with a finite difference computation [68]
∇ \left( \frac{1}{\rho} \nabla p \right)_i = \sum_j m_j \frac{8}{(\rho_i + \rho_j)^2} \frac{(p_i - p_j) \mathbf{r}_{ij} \nabla_i \nabla_j W_{ij}}{|\mathbf{r}_{ij}|^2 + \eta^2} \tag{27}

where, \eta is a small value (e.g. 0.1 \times h) to ensure the denominator always remains non-zero. Likewise, \nabla \cdot \mathbf{v}^* in Eq. 26 is discretised in SPH using the following equation

\nabla \cdot \mathbf{v}^*_i = \rho_i \sum_j m_j \left( \frac{\mathbf{v}_j}{\rho_j^2} + \frac{\mathbf{v}_i}{\rho_i^2} \right) \cdot \nabla_i W_{ij} \tag{28}

Discretisation of the PPE equation leads to a system of linear equations, \mathbf{A} \mathbf{x} = \mathbf{b}, in which \mathbf{x} is the vector of unknown pressure gradients to be determined, and the matrix \mathbf{A} is not necessarily positive definite or symmetric. In the present work, the bi-Conjugate Gradient algorithm [70] was used to solve this set of equations.

The new particle positions are finally obtained using

\mathbf{r}_{t+1} = \mathbf{r}_t + \frac{(\mathbf{v}_t + \mathbf{v}_{t+1})}{2} \Delta t \tag{29}

**Boundary and initial conditions**

One of the challenges in the SPH method is the implementation of proper physical conditions at solid boundaries. In the work here, these boundaries were modelled using two types of virtual SPH particles as illustrated in Figure 2. Similar to what was done in Libersky et al. [71], the virtual particles of the first type (shown in orange in Figure 2) fill the interior of the solid by placing them as a mirror image to any fluid particles that fall within the smoothing area \lambda h_i outside the solid. These virtual particles have the same density and pressure as the corresponding real particles, but opposite velocities. These virtual particles are insufficient to prevent the real fluid particles from penetrating into the solid on occasion. To overcome this issue, virtual particles of a second type (shown in red in Figure 2) are located at the fluid/solid interface as done in Monaghan [72]. These particles, which are fixed, interact with the fluid particles via an expression similar to that of Lennard-Jones

\mathbf{F}_{\text{rep}} = \begin{cases} \varepsilon \left[ \left( \frac{L_0}{r_{ij}} \right)^{12} - \left( \frac{L_0}{r_{ij}} \right)^6 \right] \frac{x_{ij}}{r_{ij}^2} & r_{ij} \leq L_0 \\ 0 & r_{ij} > L_0 \end{cases} \tag{30}

where \varepsilon is a parameter chosen to be of the same scale as the square of the largest velocity, \( L_0 \) is the initial distance between the particles that was calculated using the number of SPH particles and size of the domain, and \( x_{ij} \) is vector between particles \( i \) and \( j \).
Periodic boundary conditions were applied in all three dimensions for the benchmark problem, whereas they were applied only in the flow direction for the μPB work.

The fluid particles were initially distributed on a regular grid with spacing of $h = 1.5L_0$, where $L_0$ is the initial distance between particles. The number of SPH particles was also chosen based on this initial arrangement. The fluid, which was initially at rest, was driven by a body force that yielded the desired flow rate.

**Benchmarking**

The accuracy of the SPH model was verified by comparing an experimental drag correlation [73] against that obtained by solving for the flow around a sphere in a periodic simulation cell with the details given in Table 1. The drag force experienced by the sphere, $F_d$, was computed by integrating the pressure and viscous stresses around the surface of the sphere to obtain the resultant pressure and viscous forces on the surface. Because of the symmetry of the flow, both of these resultant forces are directed downstream. It was found that one-third of the drag force could be attributed to the pressure force (pressure drag) with the remaining two-thirds being due to the viscous force (viscous drag), in line with literature for $Re \ll 1$ [74, 75]. Figure 3 shows the drag coefficient obtained from SPH and the experimental correlation, where the coefficient is defined by

$$
C_d = \frac{2F_d}{\rho u_0^2 A}
$$

(31)

where $\rho$ and $u_0$ are the fluid of density and superficial velocity, respectively, and $A$ is the projected cross-sectional area of the sphere. This figure shows that the SPH predictions tend to fall slightly above that of the correlation until $Re \sim 0.05$, with the average deviation being around 5%, whereupon it passes below the correlation with a similar deviation.

Micro-packed bed

For simulation of flow through a \(\mu\)PB, the positions of the solid particles for beds of varying bed-to-particle diameter ratios were determined from experiment using a method developed by the authors [42, 43]. SPH-based simulation of flow in the \(\mu\)PBs was undertaken as explained in the following; the associated simulation parameters are given in Table 2. In order to allow solution of the flow problem through the \(\mu\)PBs using a single CPU, they were divided into \(N_n\) computational cells as illustrated in Figure 4. The simulation was then initiated by solving the flow through first cell, \(N_1\) under periodic boundary conditions in the flow direction until the pressure drop in the flow direction stabilised. At this point the SPH particles were then allowed to pass into the next cell, \(N_2\), and the process repeated. This was in turn repeated for all cells
until all the cells along the bed length had been considered. The pressure drop across the entire μPB was equated to the pressure at the outlet of this last cell, \( P_n \). The number of cells considered, \( N_n \), was dictated by the need for the pressure gradient to no longer vary with the number of cells.

4. Results and Discussion

Figure 5, which shows the pressure drop as a function of the superficial velocity for µPBs of varying bed-to-particle diameter ratios, clearly indicates that Darcy’s law holds for the systems considered here. Linear fits to these data were excellent, with all lines passing through the origin with $R^2$ being 96% or better. This figure shows that the pressure drop increases with increasing bed-to-particle diameter ratio, consistent with the fact that the surface area per unit volume of the µPB increases as the particle size diminishes relative to the bed size.

Figure 5. Pressure drop variations against superficial fluid velocity for different bed-to-bed particle diameter ratios equal to: 5.2 (solid diamonds); 5.8 (solid triangles); 6.6 (solid squares); 7.5 (solid circles); 10.4 (open diamonds); 11.6 (open triangles); 13.1 (open squares) and 15.1 (open circles), with the best fit straight lines (dash lines).

Figure 6 shows the dependence of the µPB permeabilities predicted here, which are derived from the slopes of the lines in Figure 5 as per Darcy’s Law in Eq. 1, with the bed-to-particle diameter ratio. This figure shows that the SPH-derived permeability decreases with the bed-to-particle diameter ratio in a non-linear manner to reach what appears to be a plateau at the upper end of range that corresponds well to the values predicted by Ergun’s expression, Eq. (2), which are also shown in this figure. The SPH-derived permeabilities do not, however, match those predicted by the Ergun equation at lower bed-to-particle diameter ratios except at $D/d_p = 5.8$, where the two crossover. The fact that the SPH-derived results approach that yielded by the Ergun equation at the upper end of the bed-to-particle diameter ratio strongly supports the validity of the SPH results. The deviations at lower bed-to-particle diameter ratios, on the other hand, suggests that wall effects are important for µPBs whose bed-to-particle diameter ratio is
less than 10, although this limit could be located between this value and that associated with the next smallest ratio investigated, $D/d_p = 7.6$. The decreasing trend to a plateau is consistent with the bed-to-particle diameter ratio dependency of the bed porosity shown in the insert as well as the volume-fraction of the bed over which the wall has a direct influence.

![Graph showing permeability change of µPBs with bed-to-particle diameter ratio as predicted here (open circles) and from the Ergun equation, Eq. 2, (open squares); the corresponding dependence of bed porosity is shown as an insert [43]. The uncertainties in the permeability data is less than the size of the symbols. The broken and solid lines are a guide to the eye only for the permeability predicted here and the porosity, respectively.](image)

**Figure 6.** Permeability change of µPBs with bed-to-particle diameter ratio as predicted here (open circles) and from the Ergun equation, Eq. 2, (open squares); the corresponding dependence of bed porosity is shown as an insert [43]. The uncertainties in the permeability data is less than the size of the symbols. The broken and solid lines are a guide to the eye only for the permeability predicted here and the porosity, respectively.

Figure 7 compares the SPH-derived permeabilities of the µPBs with counterparts obtained from the correlations outlined in the Introduction of this paper; deviation of the points from the broken line indicate a discrepancy between the two permeability estimates. The corresponding bed-to-particle diameter ratios are shown in descending order on an axis on the right hand side of the figure to aid understanding. The SPH results compare most favourably to the values derived from the expression of Reichelt [57], where the average and median differences are 50% and 26%, respectively. The estimates yielded by the model of Foumeny [46] are on average around 90% out from the SPH-derived results (average of 87%, median 91%). The remaining models derived for macroscale packed beds that include the bed-to-particle diameter ratio all deviate substantially, 160% to 344% median differences, from the SPH-derived results. As the SPH-derived results appear to match well the Ergun estimate at larger bed-to-particle diameter ratios, the larger deviations seen here for the Eisfeld & Schnitzlein [45], Raichura
[60], Cheng [58], and Di Felice & Gibilaro [61] suggest these models are not appropriate for µPBs.

Figure 7. Comparison of the µPB permeability obtained by simulation with those determined via existing correlations determined from macroscale beds: Eisfeld & Schnitzlein (solid triangles); Reichelt (open triangle); Raichura (solid circles); Cheng (open circles); Di Felice & Gibilaro (solid squares) and Mehta & Hawley (open squares) and Foumeny (solid diamonds).

The variation of the porosity and axial fluid velocity with position across the radius of the µPBs is shown in Figure 8 for the bed-to-particle diameter ratio of 15.1; the results are similar for all the other µPBs considered here. It can be seen in this figure that the porosity in the µPB decreases from unity at the wall to the bulk value in a damped oscillatory way some three particle diameters in from the wall. This inhomogeneity in the bed porosity leads to significant radial variation in the axial fluid speed, with the speed being locally maximal where the porosity is also similarly maximal. The velocity non-uniformity is significant with the velocity close to the walls some 2.5 to 3 times greater than the average dropping to near-zero at \(d_p/2\) from the wall before becoming constant at around \(3d_p\) from the wall in line with previous work of others [76, 77]. In contrast to Giese and Magnico studies [76, 77], the first peak is higher than the second peak at one particle diameter wall distance, although this is in line with model prediction of Cheng and Yuan [78] and simulation results [79, 80]. This clearly has performance
implications for µPBs compared to their macroscale counterparts, suggesting that models for their performance (e.g. heat and mass transfer characteristics) may not be appropriate for µPBs [35, 46, 47].

Figure 8. The variation of µPB porosity (solid circles) and dimensionless velocity (solid squares) against distance from wall for $d_p = 26.5 \mu m$ and $D/d_p = 15.1$.

5. Conclusion

The hydrodynamic character of micro-packed beds (µPBs) have been investigated as a function of bed-to-particle diameter ratio, $D/d_p$, using smoothed-particle hydrodynamic (SPH) simulation on models of the beds derived from X-ray microtomography. The permeabilities obtained from this work were in line with that given by the Ergun model for $D/d_p > 10$, suggesting the SPH results are valid. The permeability decreased with the bed-to-particle diameter ratio in a non-linear manner from around $10^{-5} \text{ mm}^2$ for the smallest ratio ($D/d_p = 5.2$), in line with a similar trend for the porosity change and volume of the ‘wall region’ relative to the total bed volume.

Comparison of the SPH-derived results with a variety of models developed for accounting for bed-to-particle diameter ratio in macroscale packed beds suggests that the model of Reichelt [57] may be suitable for estimating the permeability of µPBs, although the model of Foumeny [46] also yielded estimates that deviated less than 100% from the SPH results on average. The estimates yielded by the models of Eisfeld & Schnitzlein [45], Raichura [60], Cheng [58], and Di Felice & Gibilaro [61] all deviated significantly from the SPH-derived results. The largely
empirical nature of these longer-standing macroscale-based models means it is difficult to discern the origins of these poor comparisons.

Finally, it is also shown that the local axial flow velocity in the μPBs is inhomogeneous, with channelling being observed to occur not only at the bed wall, but also within the bed due to oscillatory porosity variation with radius. This suggests that performance models derived for macroscale beds may not be suitable for μPBs. The work here suggests that the approach taken here could not only form a sound basis for predicting the hydrodynamic character of μPBs, but also their heat and mass transfer and reaction characteristics.

Acknowledgement

A part of code implemented for this research was run on the cluster super-computational facilities and high-performance computing (HPC) system in the eResearch SA organization. MNK and HEB also acknowledge the University of Adelaide for their IPRS, APA and ASI PhD scholarships.
