Sleep disturbances are one of the most common nonmotor complaints in Parkinson’s disease (PD) and have been attributed to a variety of factors. Understanding the relative contribution of each is crucial to identify the most effective treatment strategies for individual patients. Some of these relate to the clinically identified features of the disease such as motor impairment, nocturia, pain, or neuropsychiatric symptoms. Dopaminergic and other medications may also exacerbate patients’ sleep problems. However, the sleep dysfunction in PD may be a result of neuronal loss in key structures and circuits involved in the regulation of the sleep-wake cycle.

Two recent studies have reported that reduced melatonin output in PD patients is associated with altered sleep architecture, including reduced slow wave and rapid eye movement sleep1 and excessive daytime sleepiness.2 Altered melatonin patterns have also been observed in Huntington’s disease3 and Alzheimer’s disease,4 both of which have prominent sleep and circadian abnormalities. Because melatonin is a hormone produced by the pineal gland under circadian control, we hypothesised that degenerative changes to the neural structures controlling pineal function (especially the suprachiasmatic nuclei [SCN] of the anterior hypothalamus) may reduce melatonin output and contribute to certain aspects of sleep dysfunction in PD.

This study compared hypothalamic volumes in PD patients with matched controls and determined whether volume loss correlated with reduced melatonin output in the PD group.

**Methods**

**Patients**

A total of 12 PD patients were selected from a previously studied sleep cohort.1 All of the patients who had also undergone magnetic resonance imaging (MRI) as part of the parallel Incidence of Cognitive Impairment in Cohorts with Longitudinal Evaluation–Parkinson’s Disease (ICICLE-PD) study were included in the analysis, in addition to 12 unrelated matched controls from the Medical Research Council Cognition and Brain Sciences Unit healthy volunteer panel. The ICICLE-PD protocol has been published elsewhere.5 All participants provided written consent, the study was performed according to the Declaration of Helsinki, and the protocol was approved by the local research ethics committee.

In brief, patients underwent a battery of clinical tests including the Unified Parkinson’s Disease Rating Scale (MDS-UPDRS), Addenbrooke’s Cognitive Examination (ACE-R), and the Beck Depression Inventory (BDI). Levodopa equivalent dose (LED) was calculated using the conversion factors proposed by Tomlinson and colleagues.6 Matching was based on age, gender, years of education, and ACE-R.

**Imaging Acquisition and Analysis**

MRI data were acquired using a Siemens TIM Trio 3T scanner (Siemens Medical Systems, Erlangen, Germany). Patients underwent T1-weighted magnetisation prepared rapid gradient echo scanning: pulse repetition = 2250 ms, echo time = 2.98 ms, flip angle = 9°, time delay = 900 ms, 256 × 256 mm field of view, 192 × 1 mm slices). Images were preprocessed according to a pipeline in SPM8 (http://www.fil.ion.ucl.ac.uk/spm) run on Matlab 7 (Mathworks, Natick, Massachusetts). T1-weighted images were segmented into gray matter and white matter tissue and registered through the Diffeomorphic Anatomical Registration Through Exponentiated Lie Algebra scheme. The resulting study-specific template was registered to Montreal Neurological Institute space, and individual modulated images were smoothed with an 8 mm, full width at half-maximum Gaussian kernel. A hypothalamic region of interest (dilated by 3 mm) from the
WFU Pick Atlas (http://fmri.wfubmc.edu/software/pickatlas) was used to obtain an individual hypothalamic volume per participant (Fig. 1A,B). Gray matter volume in the region of interest (measured in voxels) was calculated using the FMRIB Software Library (FSL) tool “fslstats” within FSL version 4.1.7 (www.fmrib.ox.ac.uk). Thereafter, relative hypothalamic gray matter volume was calculated by dividing by whole brain volume (both measured in voxels). [Color figure can be viewed in the online issue, which is available at wileyonlinelibrary.com.]

**Serum Melatonin Measurement**

PD patients were admitted to a single room at the Wellcome Trust Clinical Research Facility at Addenbrooke’s Hospital in Cambridge. A peripheral venous cannula was inserted 30 minutes before the start of sampling at 1:00 PM. During the next 24 hours, participants adhered to their habitual bed times, and blood samples were collected every 90 minutes using a 3-way valve that was attached to a 0.9% sodium chloride infusion to prevent the cannula from clotting. Sampling was performed through a long line to prevent disruption to the patient’s sleep. Participants remained sedentary apart from bathroom visits. Meal times were consistent between participants, and no daytime naps were allowed. Temperature was constant at 21°C. Patients were not strictly shielded from external light, but lighting levels were less than 5 lux following lights off. Serum melatonin concentrations were measured using enzyme-linked immunosorbent assays as previously described. Based on hormone

**TABLE 1. Clinical characteristics of PD patients and controls**

LED, levodopa equivalent daily dose; ACE-R, Addenbrooke’s Cognitive Examination-Revised; MDS-UPDRS, Unified Parkinson’s Disease Rating Scale; BDI, Beck Depression Inventory; na, not applicable. Results expressed as mean (SD) unless stated otherwise.

**FIG. 1.** A and B: Panels show the region of interest used to calculate the hypothalamic volume for each participant. C: Panel is a graphical representation of the significant reduction in relative hypothalamic gray matter volume in PD patients when compared with matched controls (with standard error of the mean error bars). D: Panel demonstrates the significant correlation between relative hypothalamic gray matter volume and total 24-hour melatonin output (with both axes showing partial residuals). In both graphs, relative hypothalamic gray matter volume was calculated by dividing gray matter volume by whole brain volume (both measured in voxels). [Color figure can be viewed in the online issue, which is available at wileyonlinelibrary.com.]
concentrations at each 90-minute time point, total 24-hour melatonin output was defined as the area under the curve (calculated using the trapezoid rule).

**Statistical Analysis**

All data were approximately normally distributed based on Shapiro-Wilk testing; therefore, unpaired t-tests were used to compare clinical parameters and volumetric values between patients and controls. Pearson rank correlation testing was used to study the relationship between melatonin output and relative hypothalamic gray matter volume, as well as the relationship between melatonin output and disease severity (adjusted for LED).

**Results**

Age, gender, duration of education, and ACE-R were not significantly different between PD patients and controls (Table 1). PD patients had a mean disease duration of 3.3 years, mean LED of 366 mg, and mean UPDRS part III score of 23.9. None of the participants were taking hypnotics. The mean duration between melatonin testing and MRI in the PD group was 1.9 months (SD 3.4).

When compared with controls, PD patients had significantly reduced relative hypothalamic gray matter volume (2.56 × 10⁻⁷ [SD 2.78 × 10⁻⁷] vs 2.69 × 10⁻⁷ [SD 2.07 × 10⁻⁷]; P = .005) (Fig. 1C).

Having verified that there were significant differences between patients and controls in terms of hypothalamic volume, we found that melatonin levels were significantly associated with relative hypothalamic gray matter volume in the PD group (r = .591, P = .028) (Fig. 1D). Partial correlation between melatonin levels and disease severity, correcting for LED, showed a significant inverse relationship (r = -.681, P = .021). There was no significant relationship between melatonin output and LED (r = .180, P = .76).

**Discussion**

There is increasing evidence from clinical and animal studies that there is circadian dysregulation in a variety of neurodegenerative diseases. We previously reported significant reductions in melatonin concentration in 30 early-stage PD patients. Videnovic and colleagues also found a significantly diminished amplitude of melatonin secretion in serum samples of 20 PD patients on dopaminergic therapy under modified constant routine conditions.

There is evidence from neuropathological and imaging studies that the hypothalamus is directly affected by PD. The central clock within the hypothalamus, the SCN, is likely to contribute to this volume loss because it has been shown that mice overexpressing alpha-synuclein exhibit a reduced SCN firing rate. This could weaken their ability to communicate neural and hormonal signals from the central clock to the pineal gland, which secretes melatonin into the blood.

This study thus adds to the existing literature by suggesting that hypothalamic volume loss—which we have now shown in this new PD cohort—may be responsible for reduced melatonin output, which has been linked to sleep disturbances in PD.

The major limitation of this study is the relatively small number of patients, which precluded the use of linear regression and adjustment of confounders. Furthermore, patients were not strictly shielded from external light during the melatonin sampling period, which may have influenced the results. Although we lacked serum melatonin measurements in the control group, the critical test for our hypothesis was the correlation between hypothalamic volume and melatonin levels in PD patients. It is not yet possible to perform dedicated imaging of the SCN within the hypothalamus using 3Tesla MRI; therefore, ultra-high field imaging or clinico-pathological studies will be required to allow more thorough dissection of the relative role of the different hypothalamic nuclei to this deficit.

In summary, we have shown that melatonin levels are associated with hypothalamic gray matter volume loss and disease severity in PD patients. This provides anatomical and physiological support for an intrinsic sleep and circadian phenotype in PD and the fact that this is related to the disease itself rather than being an indirect consequence of other symptoms or treatments.

**Acknowledgments:** We would like to thank Dr. Saber Sami for his assistance with imaging acquisition and Dr. Noham Wolpe for his technical support. We would also like to thank the staff at the Wellcome Trust Clinical Research Facility in Addenbrooke’s Hospital, Cambridge, for performing the melatonin blood sampling.

Abstract

Background: Parkinson’s disease (PD) and dementia with Lewy bodies (DLB) are Lewy body diseases characterized by similar pathological features. Several studies have shown a relation between alterations in the glucocerebrosidase gene (GBA) and the development of LB diseases. Here, we explored the role of GBA mutations in Spanish DLB patients.

Methods: GBA mRNA sequences were analyzed in a neuropathological (50 DLB, 43 PD, and 34 control individuals) and in a clinical cohort (47 DLB patients and 131 unaffected individuals).

Results: Sixteen GBA mutation carriers were identified, 5 of which were brains with pure DLB. The most common mutation, E326K, was strongly associated with pure DLB and PD with dementia. GBA mutations were overrepresented in men and associated with earlier DLB onset.

Conclusions: GBA mutations are also an important risk factor for DLB development in the Spanish population, are associated with earlier disease onset, and are more prevalent in men. © 2015 International Parkinson and Movement Disorder Society

Key Words: GBA mutations, Parkinson’s disease, dementia with Lewy bodies

Both Parkinson’s disease (PD) and dementia with Lewy bodies (DLB) are characterized neuropathologically by the presence of α-synuclein-immunopositive Lewy bodies (LBs) in the brain.1 Their morphological substrate is the same, and although the clinical course of DLB and PD with dementia (PDD) differs, it is difficult to detect neuropathological differences between the 2 conditions. When LB pathology represents the main neuropathological finding, cases are classified as pure LB pathology, and when concomitant Alzheimer’s disease (AD) pathology is present as common LB pathology,2 About 20%-50% of PD patients develop dementia 10 to 15 years following PD diagnosis, and its incidence increases with age and disease duration.3,4

The lysosomal enzyme glucocerebrosidase (GCase) is responsible for the breakdown of glucocerebroside into glucose and ceramide.5 Mutations in the GCase gene GBA cause GCase deficiency,6 leading to lysosomal glucocerebrosidase accumulation, resulting in Gaucher’s disease (GD).5 Because PD is more frequent in first-degree relatives with GD,7-9 GBA has been studied in PD and later also in DLB patients, showing a strong association between GBA mutations and synucleinopathies.10-16 Two extensive multicenter studies confirmed the strong association between GBA mutations and PD as well as DLB, with odds ratios of 5.43 and 8.28, respectively.17,18

The reduction of GCase levels in PD is associated with an increase in abnormal α-synuclein accumulation.16 Two models that aim to explain the role of GBA mutations for LB disease development are a gain-of-function model and a loss-of-function model. Supporting the first hypothesis, GBA mutants were found to enhance α-synuclein accumulation.19 In the loss-of-function model, lysosomal glucocerebrosidase accumulation directly promoted the formation of α-synuclein fibrils, which inhibit GCase activity, creating a bidirectional pathogenic loop.20

Although several studies have shown the association between GBA mutations and LB diseases in diverse populations, only 1 work evaluating the role of GBA mutations in PD has been carried out in the Spanish population.21 Here, we have characterized GBA...
