Abbreviations & Acronyms
BOO = bladder outlet obstruction
DO = detrusor overactivity
IPSS = International Prostate Symptom Score
LUTS = lower urinary tract symptoms
Nvoids = number of voids
PVR = post-void residual
Qmax = maximum flow rate
QOL = quality of life
Vblad = bladder volume
Vvoid = voided volume

Objectives: To develop a per-patient volume correction for maximum flow rate using multiple home uroflowmetry, and to carry out a pilot study to determine the most prognostically useful volume at which to evaluate this measurement and estimate its relationship with outcome from disobstructive bladder outlet surgery.

Methods: A total of 30 men carried out home uroflowmetry using a portable device and completed symptom scores before surgery. This was repeated at least 4 months after surgery. For each man’s presurgery flow data, voided volume was plotted against maximum flow rate, and a line of best fit with logarithmic form calculated. This allowed maximum flow rate to be corrected for any volume. Percentage reduction in symptom score and increase in mean maximum flow rate were correlated with volume-corrected maximum flow rates.

Results: Corrected maximum flow rate at all volumes showed the expected negative correlation with both outcome measures. A statistically significant correlation occurred for volumes >190 mL, with the best performance at volumes >300 mL.

Conclusions: We have devised a novel method allowing estimation of maximum flow rate at any volume, which is a step forward for non-invasive diagnostics. We found this volume-corrected maximum flow rate to correlate significantly with treatment outcome at sufficiently high volumes.

Key words: bladder outlet obstruction, home monitoring, nomograms, transurethral resection of prostate, uroflowmetry.

Introduction

The decision to carry out surgery for BOO in men with LUTS is guided by uroflowmetry. Typically a one-off measurement of Qmax is obtained using office-based uroflowmetry. There is evidence that when multiple measurements of Qmax are made for an individual, either the highest or average Qmax improves diagnostic accuracy for BOO.

Ideally, in order to control for dependency on Vblad, Qmax should be measured at a specific volume, but this is impractical. Clinical guidelines recommend that the Vvoid should be at least 150 mL, but this is not always feasible for men with habitual low Vvoid.

Nomograms have been developed enabling Qmax to be evaluated in the context of Vblad or Vvoid using relationships derived from large groups. However, the relationship between Qmax and volume varies between individuals. These nomograms do not necessarily improve diagnostic accuracy, because a larger volume might not actually mean an increased Qmax in a particular individual.

We aimed to develop a per-patient correction for flow rate using multiple measurements of Qmax and Vvoid from home uroflowmetry, and carry out a pilot study to determine the most prognostically useful volume at which to evaluate this derived measurement of Qmax and estimate its relationship with outcome from surgery for BOO.

Methods

All men scheduled for bladder outlet surgery for LUTS within the Freeman Hospital, Newcastle Upon Tyne, UK, were eligible for invitation into the study. Exclusion criteria were the
presence of an indwelling urinary catheter or need for intermittent self-catheterization. After research approvals and written consent, each man was given a home uroflowmeter and asked to record as many voids as possible for 1 week. They also completed an IPSS questionnaire. This assessment was repeated at least 4 months after surgery. The decision to carry out surgery was made before study enrollment.

The objective outcome from surgery was defined as the increase in mean $Q_{\text{max}}$ measured by home uroflowmetry. Symptom outcome from surgery was defined as the percentage reduction in total IPSS score.8,9

The home flowmeter (Fig. 1) was developed in the Regional Medical Physics Department, Newcastle Upon Tyne Hospitals NHS Foundation Trust. It consists of a jug that is placed on a measurement base unit before voiding into the jug. Volume and flow rate are measured by a weight transducer. It is intended for unsupervised use by patients, and is designed for ease of use, with no controls. It records all voids onto inbuilt memory for up to 2 weeks, after which data are downloaded to a computer. Software obtains $Q_{\text{max}}$, $V_{\text{void}}$, date, time, duration and a flow trace for each void. The accuracy of its volume and flow rate measurements is within ±5% relative to full scale (1000 mL and 50 mL/s, respectively), as recommended by the current clinical guideline at the time.10 Each void was checked visually to verify, and if necessary correct, automated calculation of void start, void end, $V_{\text{void}}$ and $Q_{\text{max}}$.

Urine flow rate depends on $V_{\text{blad}}$.11 Hence Siroky et al. developed nomograms relating flow rate to $V_{\text{blad}}$ according to a polynomial relationship. The home flowmeter measures $V_{\text{void}}$, requiring assessment of PVR for $V_{\text{blad}}$ to be known.12 At present, there are no tools available for patients to measure their own PVR at home after each void. We therefore used $V_{\text{void}}$ as a surrogate for $V_{\text{blad}}$. Using measurements of $Q_{\text{max}}$ and $V_{\text{void}}$ from presurgery home uroflowmetry, we planned to calculate an equation of best fit for each man in order to predict $Q_{\text{max}}$ from $V_{\text{void}}$. This required selection of the form these equations would take. The Liverpool nomograms are the most widely cited nomograms relating $Q_{\text{max}}$ to $V_{\text{void}}$ in men. They were constructed from single measurements of flow obtained from 331 male volunteers with no history of LUTS or bladder-related surgery.6 The nomograms are based on equation (1).

$$
\sqrt{(Q_{\text{max}})} = 2.37 + 0.18 \times \sqrt{(V_{\text{void}})} - 0.014 \times (\text{age})
$$

Two nomograms were chosen with 35 and 60 years for the age term, representing the median ages of the <50 years and ≥50 years cohorts, respectively. We therefore selected a square root relationship for the equations used to predict $Q_{\text{max}}$ from $V_{\text{void}}$ before surgery for each man. The equations took the form shown in equation (2).

$$
\sqrt{(Q_{\text{max}})} = (\beta_1) \times \sqrt{(V_{\text{void}})} + (\beta_2)
$$

Coefficients $\beta_1$ and $\beta_2$ were unique for each patient. These parameters were calculated using MATLAB vR2012 software (MathWorks, Natick, MA, USA) to minimize the residual sum of squares between the line described by this equation and the $Q_{\text{max}}$ values recorded by the home flowmeter. A point at $(V_{\text{void}}, Q_{\text{max}}) = (0, 0)$ was included for calculating the coefficients. To illustrate this methodology, Figure 2 shows examples of this equation for two patients, superimposed over the Liverpool nomogram for men aged ≥50 years. Using these equations, a set of “volume-corrected” $Q_{\text{max}}$ ($Q_{\text{max}@\text{Vol}}$) values for each individual was calculated for volumes from 0 to 500 mL at 5-mL intervals, as shown in Figure 3. At each volume, the corrected $Q_{\text{max}}$ values for the group were correlated with outcome using Spearman’s rank, giving a correlation coefficient (rho) and $P$-value. This allowed calculation of the volume at which the $Q_{\text{max}@\text{Vol}}$ values performed best in terms of predicting outcome in the study population.

For this feasibility study, we considered that results from a group of 30 men would be sufficient to determine feasibility of the use of home uroflowmetry and analyses in this context, and to estimate the predictive value for treatment outcome to power follow on studies.12 Statistical analyses were carried out using MATLAB vR2012 software.

**Results**

We recruited 33 men between January and September 2012. One man withdrew after the first period of recording because of ill health, a second man’s prostate procedure was delayed, preventing collection of outcome data and a third participant’s operation was postponed after heart surgery. This left 30 datasets available for analysis. The surgical procedures carried out for these 30 men, all for relief of BOO, were: diathermy transurethral resections of the prostate (19); holmium laser enucleation of the prostate (7); potassium titanyl phosphate laser vapourisation of the prostate (3); and holmium laser incision of the prostate (1). Table 1 presents the age and home uroflowmetry statistics for each patient. The median (25–75th percentile) age of men who completed the study was 72 years (67–75 years). Although patients were instructed to use the home flowmeter for 1 week, several continued to do so for longer, for up to a maximum of 2 weeks as dictated by the device’s operational period. All voids were included for analysis. Patients recorded a mean (SD) of 54 (25) voids before surgery and 54 (21) voids after-

![Fig. 1](image-url) The device used for home uroflowmetry: the measurement base unit (left) and the jug on top of the base unit ready for use (right).
wards. The mean (minimum – maximum) number of voids recorded per day was 8 (2–15) before surgery and 6 (2–9) afterwards ($P = 3.910^{-10}$, paired $t$-test). Automated and manual calculations of $Q_{\text{max}}$ were within 1 mL/s for 91% of voids and within 2 mL/s for 95%. For $V_{\text{void}}$, 92% were within 10 mL and 96% within 20 mL. Manual verification and, if necessary, correction took between 2 and 15 min per study, depending on the number of voids recorded and corrections required.

Table 2 compares pre- and postsurgery values for mean $Q_{\text{max}}$, mean $V_{\text{void}}$, total IPSS score, IPSS QOL score, IPSS voiding subscore (sum of IPSS intermittency, weak stream and straining scores) and IPSS storage subscore (sum of IPSS frequency, urgency and nocturia). A total of 24 patients (80%) experienced a significant increase in $Q_{\text{max}}$ after surgery, and 16 (53%) experienced a significant increase in $V_{\text{void}}$ ($P < 0.05$, multiple measurements in each man compared before and after surgery using the independent $t$-test). The median (25–75th percentile) length of time between surgery and follow up was 170 days (156–213 days). There was no correlation between length of time from surgery to follow up and any of the following: increase in mean $Q_{\text{max}}$, increase in mean $V_{\text{void}}$ or decrease in total IPSS score (all $P > 0.05$, Spearman’s rank).

For every patient, $Q_{\text{max}}@\text{Vol}$ was calculated at 5-mL intervals from 0 to 500 mL from presurgery home uroflowmetry data. At all volumes, $Q_{\text{max}}@\text{Vol}$ for the group showed the expected negative correlation ($\rho < 0$) with both outcome measures, showing that men with lower presurgery flow rates tended to experience better outcomes. $Q_{\text{max}}@\text{Vol}$ values for volumes above 190 mL correlated significantly ($P < 0.05$) with both objective and symptom outcome. Figure 4 shows how rho and $P$-values changed depending on the volume at which $Q_{\text{max}}@\text{Vol}$ was corrected. For objective outcome, correlation improved with increasing volume, plateauing at 300 mL, where rho was less than –0.46 (95% confidence interval –0.12 to –0.70) and $P < 0.01$ (moderate correlation; Fig. 4a). A similar, but less pronounced, pattern was observed for the correlation between $Q_{\text{max}}@\text{Vol}$ and symptom outcome (Fig. 4b). Figure 5 shows volume-corrected...
Given that the flow rate is reported to the nearest 1 mL/s, it would be sensible to record enough voids such that inclusion of additional voids does not change \( Q_{\text{max}} \) at 300 mL by more than \( \pm 0.5 \text{ mL/s} \). This was calculated for each individual, and the highest void number at which this occurred was 21. We defined a man’s \( Q_{\text{max}} \) relationship as one that “fit” the Liverpool nomogram if it intersected fewer than two of the Liverpool centile lines for \( V_{\text{void}} > 100 \text{ mL} \). Accordingly, 14 (47%) did fit the Liverpool nomogram (e.g. Fig. 2a) and 16 (53%) did not (e.g. Fig. 2b).

**Discussion**

Use of a single volume-corrected \( Q_{\text{max}} \) or nomogram categorization of \( (V_{\text{void}}, Q_{\text{max}}) \) is used as a method to decide whether an individual’s \( Q_{\text{max}} \) is abnormally low, in order to determine the likelihood of BOO and guide clinical management. Methods reported previously have derived a relationship between volume and \( Q_{\text{max}} \) using a single or small number of voids from each individual in a large group of asymptomatic men.

![Fig. 4 Variation in rho (•) and P- (▲) values with volume for the correlation between \( Q_{\text{max}} @ \text{Vol} \) and (a) objective surgical outcome (increase in mean \( Q_{\text{max}} \) from the home flowmeter) and (b) subjective surgical outcome (percentage decrease in total IPSS score).](image-url)

</table>

Either $V_{\text{void}}$, measured by the flowmeter, or $V_{\text{blad}}$, determined by summing $V_{\text{void}}$ and PVR, have been used. A single flow measurement from a man with LUTS is then evaluated in this context. This approach risks poor diagnostic and prognostic accuracy if the patient under assessment does not show the assumed relationship between $Q_{\max}$ and $V_{\text{void}}$. Sonke et al. found this relationship to differ considerably between individuals, with one-third having a negative relationship (decrease in $Q_{\max}$ with increasing $V_{\text{void}}$). Only a large number of measurements obtained from an individual allow their true relationship to be determined with statistical confidence. This is made possible by asking patients to carry out uroflowmetry on multiple occasions at home, or elsewhere, during their day-to-day life.

A group of men with LUTS will include men with BOO, men with DO, men with both BOO and DO, and men with neither. Bladder outlet surgery is thought to achieve better outcomes in men with BOO than those without, and symptoms associated with DO in men with BOO have been observed to improve after disobstructive surgery. Ideal candidates for surgery are therefore men with BOO, with or without coincident DO. A one-off measurement of flow with low $V_{\text{void}}$ and low $Q_{\max}$ cannot differentiate a man with BOO from one with pure DO, in whom disobstructive surgery is less likely to give benefit. The method presented in this study allows estimation of $Q_{\max}$ at any volume by extrapolation of serial voids, which might be low volume. This means that there is in effect no lower volume limit for flow data acquired in this way, which is a step forward for non-invasive diagnostics.

The present study, using this approach, found that a volume-corrected $Q_{\max}$ calculated for each man from paired measurements of $Q_{\max}$ and $V_{\text{void}}$ correlates well with outcome from disobstructive surgery, suggesting that it might be valuable in predicting who would benefit from surgical treatment. For objective outcome, better and statistically significant correlation was measured for volume-corrected $Q_{\max}$ at volumes of 300 mL and above, which might reflect the average volume above which the detrusor must be stretched to generate its greatest contractile force. Thus, the present results suggest that the optimum volume is at least twice the 150 mL recommended minimum $V_{\text{void}}$ for a valid office-based flow test.54

Fixing a point of origin at $(V_{\text{void}}, Q_{\max}) = (0,0)$ allows mathematical calculation of a square root relationship from just one void, but an estimate based on a few voids is inaccurate. With each additional recorded void, $Q_{\max@300}$ tends towards its true value. In the present study, for no patient was there any practical improvement in accuracy beyond 21 voids. For future larger scale independent validation studies, we therefore recommend that at least 21 voids are recorded per man for reliable calculation of $Q_{\max@300}$. All but one of our participants recorded at least this number (Table 1), despite no minimum being requested.

The process of fitting an equation to predict $Q_{\max}$ from $V_{\text{void}}$ was carried out using MATLAB vR2012 software. In future, these calculations could be built into the home uroflowmetry analysis software for presentation alongside other summary statistics from the study.

Previously, subjective outcome from surgery has been defined by percentage improvement in IPSS, with $<50\%$ classed as “poor” outcome and $\geq 50\%$ classed as “good.”9 Thus, from Figure 5b, one may apply a threshold of 14 mL/s to $Q_{\max@300}$, because at this value the line of best fit between $Q_{\max@300}$ and percentage decrease in IPSS after surgery equals 50%. A threshold approach like this is often favored for research purposes, allowing cases to be grouped and compared. However, it would be more valuable clinically to use the relationship between $Q_{\max@300}$ and outcome to inform a man of the improvements in symptoms and flow rate expected on average for a man with similar presurgery flow volume characteristics. This could inform the decision of whether or not to undergo surgery.

Few previous studies have correlated presurgery uroflowmetry parameters with outcome. Oh et al. measured in 134 men the correlations between pretansurethral resections of the prostate BOO index both pre-surgery $Q_{\max}$ from single clinic uroflowmetry ($p = 0.26$, $P = 0.002$) and improvement in IPSS storage subscore ($p = 0.19$, $P = 0.032$).12 However, this was a different population of patients, preselected according to BOO index, and using Pearson’s analysis, which produces weaker correlation for non-linear relationships.

As a feasibility study, this suffered from several limitations. Different surgical procedures were carried out, although all were carried out to relieve BOO. There was variation in the diagnostic workup and treatment history of participants, and subgroup analyses would have lacked statistical power. All patients were deemed by their urologist to be suitable for

disobstructive bladder outlet surgery, although pressure-flow studies to confirm BOO were carried out only in men with higher operative risk (fewer than half). There was variation in time between surgery and follow up for logistical reasons, but most men were reinvestigated at 4–6 months, and no difference in outcomes was observed according to time to follow up. Despite these limitations, a significant relationship between $Q_{\text{max}}@\text{Vol}$ and surgical outcome was shown. For reasons described earlier, a volume-corrected $Q_{\text{max}}$ should perform better than a single office-based measurement in terms of predicting treatment outcome. However, the lack of a direct comparison in the present study, because of the unavailability of these results in a number of participants, was another limitation.

We now plan to investigate the diagnostic and prognostic value of $Q_{\text{max}}@\text{Vol}$ in larger groups of men with LUTS. The most appropriate function to predict $Q_{\text{max}}$ from $V_{\text{void}}$ for a cohort (in this case a square root function) is not necessarily the most appropriate for each man (this is a recognized phenomenon: “Simpson’s paradox” describes the general situation where a group relationship is non-existent or reversed in the individual). There is therefore scope for further work to determine the most appropriate mathematical function to predict $Q_{\text{max}}$ from $V_{\text{void}}$ in an individual. Indeed, deviation from a normal pattern could indicate urological abnormality, and classification of $Q_{\text{max}}$ versus $V_{\text{void}}$ patterns related to different urological diseases would be of great interest. A large normative dataset and method of quantifying whether an individual fits a normal pattern are required. It would be interesting to investigate the effect of the number of voids recorded and voided volumes on the clinical value of $Q_{\text{max}}@300$.

In conclusion, we have devised a novel method for providing, for each individual, an estimate of $Q_{\text{max}}$ at specific $V_{\text{void}}$ using multiple home uroflowmetry. We found in a limited patient sample that this volume-corrected $Q_{\text{max}}$ at volumes above 190 mL correlated well with treatment outcome, with optimum volumes being 300 mL and above. Early data suggest a threshold of 14 mL/s for $Q_{\text{max}}@300$. These results can be used to power larger studies of the diagnostic and predictive value of volume-corrected $Q_{\text{max}}$ in men with LUTS.
